The *damp stove* requires treatment of an opposite description. Instead of being kept dry like the last, its atmosphere should be always excessively humid, except in the winter season, when the sky is generally cloudy, and the sun's rays weak. Various methods are adopted to keep the atmosphere in this saturated state. When the house is heated with common smoke flues, the most simple way is to throw water frequently upon them, and also upon the passages and other places, from which it will evaporate, and surround the plants with a moist atmosphere. Sometimes a channel is formed with cement, upon the upper surface of the flue, which keeps the water from running off. This is a very excellent plan, as it may be so made that it will hold a considerable quantity of water, which will be continually evaporating, and serve the same purpose as that of a person frequently throwing water upon it. When the house is heated with hot-water or steam-pipes, it is a good plan to get small ridges cast upon the sides of the pipes, if they are flat, or, if they are round, small cisterns made of lead or zinc will answer the purpose, which can be used in the same manner, and will have the same effect as the channel upon the smoke flue. With the exception of a few months in winter, the damp stove must be regularly syringed twice every day. This is indispensable to the health and vigorous growth of the plants, and also necessary in order to keep down insects. The quantity of water which the plants in this house will require depends entirely upon the state of the weather and their own growth; in winter they will need little, as spring advances they may be watered more freely, and in the summer season they will all require to be watered twice and some of them three times a-day; of course those which are growing vigorously will require the most. It is a very bad plan, although one which is too often practised, to water almost at random, giving all the plants almost an equal share, regardless of their different capacities. Some will require a very abundant and constant supply, others will almost live upon the atmospheric moisture that surrounds them. Another thing to be attended to in the treatment of this stove is the placing of the plants. Most of the kinds grow very freely, and if they have not plenty of room they will very soon get crowded, and instead of growing bushy and handsome, the result will be an unsightly specimen, with a long bare stem and a few leaves upon its top. To prevent this they must be regularly looked over, tied up, and kept clear of each other; elevating some, depressing others, and giving the whole not only enough of room but also a natural appearance. The temperature of this stove, like that of the dry-stove, should not be the same at all seasons; in winter, when the plants are in a torpid state, 55° or 60° of Fahr. is quite warm enough; when vegetation begins to take place, as spring advances, it may then be gradually raised to 70°; and during fine weather, in the middle of summer, fires may be discontinued for about three months; but this must depend entirely upon the weather. The thermometer should never be allowed to sink lower than 60°.

The *bark stove*, when it is of large dimensions, consists of a pit in the middle of the house, surrounded by a brick wall, leaving as much room round the sides as will form a passage to walk in. This pit is generally from four to six feet in depth, one-half below and the other half above the level of the floor of the house; but this depends chiefly upon the height of the roof and the object in view. In smaller houses no space is left for a passage, and the inside is entirely occupied by the pit. The pit is filled with bark (commonly called tan, from its having been used previously by the tanners), and after being allowed to sink a little and ferment, the pots containing the plants are plunged more or less deep as prudence may suggest. It is dangerous to plunge the pots too deep at first, before the heat of the bed is fully ascertained, because in that case the roots are very liable to be burned; the better way is to plunge the pots only about one-third at first, and deeper afterwards. Sometimes leaves are mixed with the tan; the reason being that they are in some parts of the country more easily procured. When the heat begins to decay, the bed must be turned over and a little fresh tan added; and whenever a new bed is made, a little of the old tan should always be mixed with the new. This stove is heated independently of the bark, of which the principal use is to warm the roots of the plants. A bark bed is found useful in the cultivation of all those kinds of plants which are grown in the damp stove; orchidaceous plants, for example, succeed admirably in this way. The treatment of it, so far as the temperature, watering, and syringing are concerned, is precisely the same as is recommended for the damp stove.

What are called *Palm-houses*, *Musa-houses*, *Orchidaceous-houses*, &c., are merely damp stoves of different dimensions, for the cultivation of those different subjects.

The only other hothouse distinct from those already noticed is the forcing-house. The treatment which this requires is essentially different from any which has been described, the object being not merely to grow the plants, or to make them produce flowers, but to obtain fruit, and that too at particular seasons. [FORCING.]

Hothouse plants are peculiarly liable to the attacks of insects, and unless carefully and constantly attended to, these little depredators do a vast deal of mischief. The most common kinds are the *Green-fly*, *Thrips*, *Red-spider*, *Brown-scale*, and *Mealy-bug*. The first of these is easily conquered by fumigating the house with tobacco, or syringing the plants with an infusion of the same substance. The best remedy for the thrips and red-spider is to syringe well, and keep the house very moist and warm, as those insects cannot live in excessive moisture; a little of the flowers of sulphur shaken upon the leaves will also destroy them. The brown-scale and mealy-bug are the worst of all that infest plants in hothouses. Bruised laurel leaves strewed upon the passages and other parts of the house are said to destroy them, but these must be used with great caution, as they may not only kill the insects, but the plants themselves. Various other substances are said to destroy them, but, after all, the best and surest remedy is to wash them off. This is perhaps rather difficult where these little intruders are numerous, but after the plants are once clean, it is an easy matter with a little attention and diligence, to keep them so.

HOT-WALL. Hot or flued walls are constructed in cold countries, for the purpose of affording warmth to trees placed against them, so as to counteract the effects of frost in autumn, when the wood and buds are maturing, and in spring, when the blossoms and leaves are unfolding. If hot-walls are used for these purposes only, they are productive of great benefit to the plants which they shelter; but if, as often happens, in addition to this it is attempted by their aid to advance the ripening of fruit in any considerable degree, hot-walls are of very doubtful service. This uncertainty of success arises from the exposed condition of the surface of the wall, and the consequent liability of the heat to be dispersed as rapidly as it is generated, either in consequence of wet causing evaporation, by which the bricks themselves are cooled, or by cold sweeping winds, which prevent any accumulation of warm air from being formed. In mild weather, a hot-wall with a south aspect will forward vegetation very considerably; but in proportion to the extraordinary excitement, so will be the check from subsequent chilling blasts which this variable climate is so subject to in the early part of the season. Besides the dissipation of heat on the south side an equal, if not a greater portion, is radiated from the north side of the wall, where it may be said to be entirely lost. It is therefore evident that wherever coals are expensive, hot-walls are not to be recommended, except for the sole purpose of rendering a little assistance towards ripening the wood in autumn, and warding off the effects of frosty nights in spring.

One furnace is allowed for heating about 40 feet of wall, that is, 20 feet on each side of the place where the fire is situated. The flues on either side are made to take four courses, or two returns; the first course being a little above the surface of the ground, and the upper 1½ or 2 feet below the coping. An improvement consists in admitting, by means of a register, a portion of the heat directly from the furnace into the second course of flues. A thick double woollen netting ought to be provided for the protection of the plants on the wall, and so attached to rollers as to be easily rolled up in fine weather, and let down at night. This, with a close-fitting wooden coping, projecting at least 12 inches, will, in a great measure, obstruct the radiation of heat. By such means very excellent crops of cherries have been obtained at an early period of the season; and as this species of fruit is precarious to force in a hothouse, a portion of a hot-wall where the trees are planted permanently may be very properly set apart for such an object.

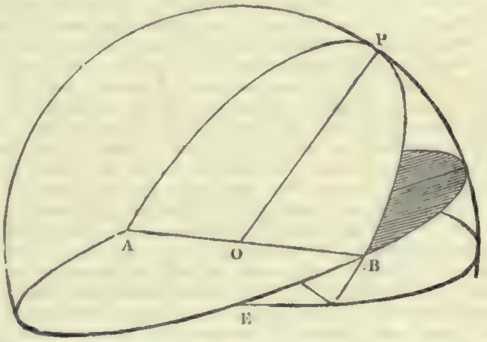
Instead of flues, hot-water pipes might be introduced into the cavity of a common hollow wall, a little above the level of the border. One range of 4-inch pipe would be sufficient for at least 200 feet of wall, the boiler being placed at the back of the wall, and having an upper and lower pipe extending 100 feet each way. If, as sometimes happens, a glass case is erected in front of a hot-wall, a hot-water pipe should be made to pass along in front of the trees, about two feet from the wall, and the return-pipe only might be placed in the cavity of the wall. A great saving of fuel would be the consequence of such an arrangement.

HOUR, HOUR-CIRCLE, HOUR-LINE. The first word always means the twenty-fourth part of a day, by what revolution soever the day may be measured. [TIME.] In angular measure [ANGLE] it signifies the twenty-fourth part of a complete revolution, or 15°.

Any great circle on the sphere which passes through the two poles is called an hour-circle, because the hour of the day is known when that circle of the kind mentioned is ascertained upon which the sun is for the time being. But the two semicircles into which the poles divide such a circle belong to different hours, and are twelve hours asunder. In fact, it is a *semi*-circle which is spoken of under the term hour-circle. [SPHERE, DOCTRINE OF.]

The hour-lines of a sun-dial are the lines on which the shadow falls at different hours, and are the intersections of the hour-circles with the plane of the sun-dial. In the times preceding the common use of clocks, the science of dialling was of considerable importance, and many works were written on the subject, in which the forms of such instruments were varied without end, and also the methods of constructing them. One work even announces "a new conceit of reflecting the sunne beames upon a diall, contrived on a plane which the direct beames can never shine upon." In the rest of this article we propose to show how to construct any plane sun-dial, or rather how to calculate the hour-lines for it by means of spherical trigonometry. A maker of sun-dials should form a table for every species of dial which he wishes to construct, once for all.

Firstly, suppose the dial to be perpendicular to the meridian, which is the case in the horizontal sun-dial and in the vertical south sun-dial. In this case the line drawn through the dial, in a vertical east and west plane, must be horizontal. The style of the sun-dial is of course to point towards one of the poles. Let O be the centre of the globe, and of SEN the circle on which the dial is to be drawn, and let SPN be the meridian, P being the north pole. Then at noon the shadow of the style (a portion of the line OP) is on ON. Let the position of the sun in the afternoon be in the plane of the hour-circle APB, and let the real solar time be h (hours or minutes), and turn h into degrees, &c., at the rate of 15° to an hour of time. Let H be the angle thus obtained. Let a be the angle by which the plane of the dial is to dip below the horizontal plane, and l the latitude of the place. Then in the right-angled spherical triangle PNB, the side PN or PC − NC is $l - a$. and the angle BPN (=SPA) is H. But NB (answering to the angle NOB) is the angle made by OB, the hour-line wanted, with ON, the noon hour-line: let it be called H′. And by the properties of right-angled spherical triangles,



$$\tan H' = \tan H \times \sin (l - a);$$

from which H′ may be calculated for as many values of H as may be necessary. If the dial be horizontal (the most common case) we have ($a = 0$)

$$\tan H' = \tan H \sin l;$$

and if the *north* side of the dial dip instead of the south, by an angle a, the formula is

$$\tan H' = \tan H \sin (l + a).$$

In the case of a vertical south sun-dial, in which the style must point towards the south pole, we have

$$\tan H' = \tan H \times \cos l.$$

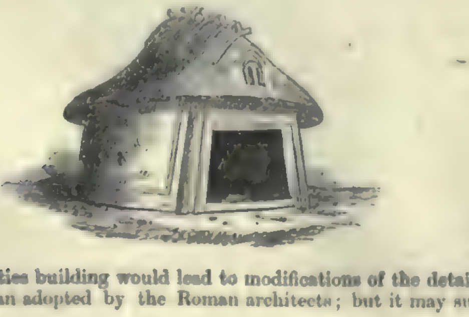
Secondly, suppose the dial to be not perpendicular to the meridian. In that case the circle SPN, perpendicular to the dial, is not the meridian, and it must be ascertained what angle it makes with the meridian, and thence, what hour-line is ON. This being found, the dial is constructed in the same manner as before, and the hour-lines follow the same law, with this exception, that the preceding formula does not measure the angles from the twelve o'clock hour-line, but from some other. It is not worth while to pursue this case further.

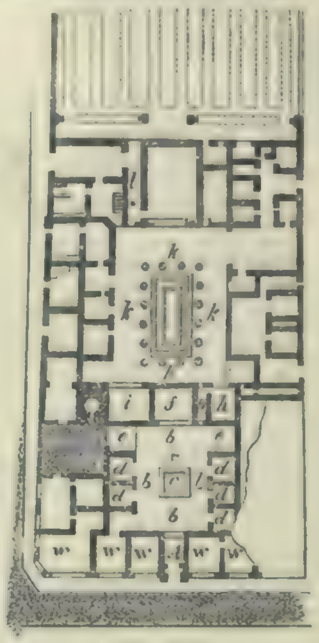
HOUSE. The buildings erected for the habitation of well-to-do private citizens, and occasionally those intended to shelter animals, or to receive particular descriptions of machinery, are generically known by the name of *houses*, in contradistinction to *palaces* and *mansions* (or the habitations of rulers in the land), and to *huts*, or *hovels*, and *caverns*, in which the very poor or the uncivilised seek protection from the inclemencies of the atmosphere. As the construction of houses must depend upon the local conditions of climate, of the materials used, and of the state of civilisation which prevails at the period of their erection, it follows that the varieties of house construction must be infinite; and it will, therefore, be advisable to limit the observations to be made on the subject to the practice which has prevailed in the most distinctly marked countries, or periods, of ancient or of modern times, in this branch of architecture.

It appears, from Sir G. Wilkinson's 'Manners and Customs of the Ancient Egyptians,' that the houses of that country, and very probably those of all the earlier nations of the East, were erected upon nearly the same plans as were subsequently followed by the Greeks and Romans, in the cases at least of the town residences of the wealthy citizens. They were usually composed of a forecourt, separated from the street by a wall, and containing a few trees, a tank, or a fountain in the centre. Doors opened from this court into a reception room, wherein the master of the house received strangers, and into passages leading on the right and the left to the dwelling rooms or the offices. In some instances it would appear that there were two, or even three, stories; but as a general rule the Egyptian houses consisted only of a ground floor, with a few rooms of inconsiderable size, and more like summer houses than dwelling apartments, upon the level of the terrace which usually covered the building. The doors and windows were closed with wood panels on hinges; the walls were constructed of crude unburnt bricks, and they were carefully stuccoed with the mouldings, pilasters, and cornices of the door dressings, executed in that material and painted to look like stone; the floors were either of stone or of a species of mortar, and the roofs were made of wood beams covered with planks, or occasionally of brick, or even of stone, vaulting. In the houses of two or more stories, the rooms upon the ground floor were used as store rooms, and those upon the upper floors were used as bed rooms or as living rooms.

The houses of Athens of the time of the republic are described as having consisted of a forecourt, or a portico, at the bottom of which was the entrance to the dwelling rooms, and these were divided into two compartments or stories, the lower one for the men, the upper one for the women. In the houses erected in Greece at the period of the Roman dominion, however, the distribution seems to have been more complicated; and, from the researches of Sir W. Gell, it may be inferred that the plan then adopted was nearly as follows:—A court surrounded by a peristyle was entered, either directly from the street, or through a passage between the stables or offices. From this court access was obtained through the Prostas to the Thalamus or Antithalamus, where the women worked, and to the Oicos, or the great dining room, around which were arranged the *hospitalia*, or strangers' rooms. The sleeping apartments of the women were on the upper floor, and they were approached by a staircase, in such a manner as to separate the *gyneconitis* effectually from the rest of the house when required. Even to a very recent period of the Grecian history the houses seem to have been constructed entirely of wood, with the exception of the roof covering of tiles; for it is to be observed, that the Oriental system of terminating the houses by a terrace was not habitually adopted in Greece, where the atmosphere was more exposed to sudden variations, and was at all times less dry than that of Asia Minor or of Africa.

When Rome had rendered herself mistress of the ancient world, and her citizens began to indulge the monstrous luxury which characterised the later days of the Roman civilisation, the style of house-building participated in the changes introduced in the manners and customs of the nation. There are no remains of the private residences of the Romans of the period anterior to the close of the third Punic war; but, from passages in Pliny and Vitruvius, it would appear that they were constructed in a very simple manner, and of rude and perishable materials. The walls were built of unburnt bricks, and were only of one story in height; the roofs were of wood, and covered with reeds or thatch; and, as might have been expected under such circumstances, whenever a fire did occur, the destruction of whole quarters of the town necessarily followed. During the later days of the republic, and, in fact, so long as the Roman empire lasted, the style of house construction, for the purposes of the wealthy portions of that strange society, was affected by the awful excess of luxury amongst the higher classes attendant upon the social organisation of the heathen world; and we consequently find that the residences of the rich were built with every imaginable refinement, while those of the poor continued to be as rude and as perishable as they were in the earlier periods of Roman history. In the first part of Mazois' 'Ruines de Pompéi,' Paris, 1824, folio, the reader will find an elaborate treatise on the habitations of the ancient Romans, with some interesting plans of houses, copied either from the relics of the most perfect remains still to be found in Italy, or from the sculptured plan of Rome, executed in the time of Septimus Severus, now existing in the Vatican; and he also gives a sketch of the original Latin dwelling, of which a reduced copy is appended by way of contrast. Of course the circumstances of the respective parties building would lead to modifications of the details of the normal plan adopted by the Roman architects; but it may suffice to observe that, wherever it was possible so to do, the various parts enumerated upon the subjoined plan were introduced, and the house of Pansa, discovered in the ruins of Pompeii, may fairly be taken as the type of the domestic architecture of the masters of the ancient world, in one of the favourite Italian provinces at least.





In this plan, the entrance from the street takes place through the *prothyrum* (A), where the porter was stationed, and which served as a passage between the shops (w w) immediately facing the street, and connected or not with the main building, as might be desired. From the prothyrum the clients, or visitors, of the proprietors passed at once into the *cavædium*, or Tuscan Atrium, surrounded by covered galleries (*b*), but having an open space in the centre (*c*), and upon the floor a basin or tank to receive the rain-water from the roofs of the galleries. [ATRIUM.] Around the cavædium were the apartments of the domestics (*d*), and some small reception rooms (*e*) for business visitors; and immediately opposite to the prothyrum were, firstly (*f*), the *tablinum*, or summer dining room, separated from the cavædium by a curtain; secondly, the (*g*) *fauces*, or passage leading to the inner apartments; and thirdly, the *cubiculum* (*h*), or bed chamber, and perhaps the *pinacotheca* (*i*), or picture gallery: the entrance to both the latter apartments was, however, from the inner court or peristyle. This *peristyle* (*k*) consisted of a large court surrounded by columns supporting a covered gallery, from which access was given to a series of apartments occupied by the members of the family, to the store closets, to the shrine of the household gods, and to the *triclinia*, or private dining rooms. There was, at the rear of Pansa's house, a garden, approached through *fauces* (*l*) on the end wall; and it would also seem that there was a series of apartments detached from the rest of the house, together with a number of shops, entered from the side streets. The shops, if we may judge from the remains of the staircases, contained two stories; but the main building was entirely upon the same level throughout. The materials employed were of the most costly description, and painting, sculpture, mosaic, marbles, inlaid woods, &c, were used with unbounded prodigality; and every precaution was observed for the purpose of regulating the uniformity of temperature in the apartments especially devoted to the uses of the family. In short, the general system of the Roman houses may be described as having consisted in the construction of separate blocks, or *insulæ*, containing one large *villa*, and a series of small shops occupied by the tenants of the principal proprietor; and the villa itself was divided into two distinct parts, one of which was devoted to the public or official duties of the proprietor, and the other to his family requirements.

During the stormy period of transition from the ancient to the modern social organisation, the traditions of Roman art continued to prevail in Europe, and the houses of the kings, and of the monastic institutions of the middle ages, were designed upon nearly the same principles as those of the Roman villas. The porch, the forecourt, the parlours, the refectories, the cloisters, and the sleeping apartments immediately around the latter, were evidently placed in imitation of the analogous parts of the Roman villas; nor was it until the abuses of the feudal system had driven the inhabitants of towns to enter into a combination for mutual defence, capable of securing the freedom of the towns, that anything like domestic architecture displayed itself. As might naturally have been expected, the first indications of this Art in the more modern times were to be traced among the Latin nations of the south of Europe; for in them the municipal life of the

Romans had passed more thoroughly into the spirit of the nation than it had done in the north; and we accordingly find that the earliest specimens of mediæval house-architecture are to be met with in Italy, Spain, or in the south of France. Some of the earliest, and the best, specimens of this phase of art are to be found in the town of Cluny, in the Department of the Soane et Loire, and in Florence, Pisa, &c. in northern Italy, where the houses though built in a sufficiently solid manner to enable their proprietors to resist a sudden attack, were evidently more adapted to the requirements of the civil life of modern societies than the immense dwellings of the ancient Romans could, by any possibility, have been made. In proportion as the middle classes rose into power and influence, the domestic architecture of Europe also assumed importance; and indeed it may be received as a general law that house building, in the meaning we usually apply to the word, owes its origin in a secondary sense, to the development of the municipal institutions which brought those classes into power at the dawn of modern civilisation. About the 12th and 13th centuries Venice, the Hanse towns, and the numerous cities of Flanders attained the apogee of their glory; and the numerous beautiful houses of that period may still be referred to with admiration, though of course the improvements in the means and appliances of domestic life have rendered the domestic architecture of this particular period inapplicable at the present day. The primary law of the development of domestic architecture will be alluded to in the sequel.

In fact, we may observe, the defective state of the municipal organisation of the middle ages in all that relates to the police, to the water supply, paving, and lighting, and the relatively small sizes of the towns, compared with those of modern times, rendered some details in the disposition of houses indispensable, or at least not objectionable, which would not now be tolerated. Thus for instance, the basements of the houses were necessarily built in a substantial manner in order to resist sudden attacks by thieves; the shops, stables, magazines were established on the ground floors, and too often actually on the ground; in the narrow-confined court-yards were placed the cesspools, and the well; and as may still be seen in the old houses of Bruges, Rouen, &c., access was gained to the upper stories by means of narrow, dark, spiral staircases. The fiscal regulations of the various states seem to have led in some cases to peculiarities in the selection of the building materials employed; as for instance when the Dukes of Normandy levied an *octroi* on stone, the inhabitants of Caen and Rouen adopted the use of wood; and, at a more recent period still when, during the reign of Louis XIV. an *ordonnance* of the police limited the height of stone walls facing upon a street, the system of wood roofs covered with lead or slate, known as the Mansard roofs, was adopted. It is to be observed that the houses built during the middle ages very rarely had party walls, and that, like the houses in the modern Dutch towns, each dwelling had its entire enclosure. Under these circumstances the architecture of each particular house had greater scope for originality; and, as in the majority of cases the gable ends of the house face the street, there is usually a very varied and picturesque sky outline in the towns of the period thus referred to. The interiors of the houses were, however, very rude, and we should now say, very uncomfortable. Ceilings were not known, the upper floors were roughly executed with wide planks nailed upon square beams; and Erasmus even tells a sad tale of the filth and abominations the floors were made to support. The windows were not always glazed; those of the shops especially being left open by day and closed by shutters at night, (just as the windows of the shops in Spain, or the less civilised nations, are at the present day) whilst heavy iron bars served to protect the openings against nocturnal marauders; signs swung over every shop, and the water from the roofs was poured directly into the street through grotesque gargoyles.

An important law with respect to the development of the intimate perception of æsthetical principles may be derived from the history of house or of domestic architecture, namely, that precisely in proportion as the individual feeling, so to speak, of the members of society was able to cast aside the trammels of the social tyranny inherent to the political organisations of the ancient world, so were the moderns able to develope a form of art which can hardly be said to have existed at a period when the only classes were the masters and the slaves, and personal liberty of action was sacrificed to the interest or to the political system of the state. Thus, in Greece and Rome we find that the palaces of the wealthy were replete with every description of luxury, and that they were built in a manner sufficiently solid to last to the present day; whilst hardly a trace can be discovered of the dwellings of the middle classes, or of the poor. During the middle ages, the feeling of individual responsibility which is the key-note, as it were, of our modern civilisation, was gradually developing itself; and when the Reformation of the 15th century brought that feeling home to its partisans and enemies alike, all the slumbering energies of our race were urged into the feverish activity which is still carrying us onwards. Domestic architecture, like every other branch of art, participated in the movement; and it is from the middle of the 16th century that we may date the greatest improvements of this branch of the arts. The houses of the period of our Elizabeth, of Henri IV., of the early days of the Dutch republic, were as distinctly in advance of the inconvenient and rudely constructed houses of the antecedent periods in their internal arrangements, as the best modern houses are in advance of them; and it is to be observed that the æsthetical character of the buildings then erected began to assume the personality of the artists, and to reflect the tastes, feelings, and modes of thought of the parties erecting them. No doubt the houses of antiquity and of the middle ages were in accordance with the spirit of their times, but that spirit was a national, a political, or a theocratic spirit, no wise a personal one; nor was it until the period of the Reformation that the style of art which gave rise to the dwellings of such towns as London, Paris, and Berlin, or Munich, can be said to have arisen. And it may also be observed that the peculiar expression of the art in every country of modern Europe may be connected with its social and political constitution; and that they who know how to observe, may easily trace the influence of national laws and national faith in every detail of house architecture in nations possessing a decided autonomy.

Without dwelling on this abstruse question, it may suffice here to say that the modern houses of the civilised nations of Europe and America may be divided into two classes, namely, those which are specially intended to receive one family only, and those which comprise several distinct residences under the same roof. Unquestionably the former class of houses is for many reasons superior to the latter, so far as regards the comfort of the inhabitants, and, it may be more than suspected, as regards its influence upon the general tone of morals, for the love of home can hardly co-exist with life in a kind of common hive; but at the same time, the larger houses which it is necessary to build for the second class admit of a bolder and more ornate style of handling, and of the introduction of a more palatial character. It thus happens that the houses of England and of Holland, where the first class of houses prevails, are deficient in grandeur of external character; and that those of France, Germany, and Italy, where the second class prevails, in the large towns at least, are so much more imposing.

It would be impossible in a short article to trace the rules which are usually adopted in the construction of either of these classes of houses with respect to their interior details; because the requirements of the tenants, their occupations, and their conditions of fortune, necessarily introduce an endless variety; and, moreover, the modifications of climate itself render it necessary to adopt different arrangements in one country from those which would prevail in another. There are, however, some invariable rules to be observed in all good house-building, which may be briefly stated as follows:—

1. The external walls must be constructed of such materials, and of such thicknesses, as to protect the dwellers in the houses from the inclemencies of the external atmosphere, and from the noise of the streets, if possible, when the houses are built in towns. Precautions must be taken to prevent damp from rising in the walls by the capillary action of their materials, and to prevent the communication of fire from house to house. None but the densest and most impermeable bricks or stones should be employed in the external walls of town dwellings, and the most decidedly hydraulic limes should be used in connection with them. In country districts the old half-timbered houses may be tolerated; but neither they nor the cob-walled houses are desirable: in order to keep the walls dry, the eaves of the roof must be continued downwards beyond the top of the wall and projected from it. As far as possible, the openings for doors and windows should be immediately over one another; and it is desirable to avoid constructing a fire-place or flue in an external wall.

2. The materials used in the interior works of houses should be of a partially absorbent and non-conducting nature in cold damp climates; but in warm dry climates, on the contrary, the denser and more rapidly conducting materials may be used. The openings made for the sake of light should be filled in with the most transparent, but also the least diathermal, glass. As far as it is possible to secure that arrangement, the openings for air and ventilation should be made in the walls exposed to the direct action of the sun's rays; and windows looking towards the north should be avoided, unless it be in tropical countries.

3. The sizes and number of rooms in houses must be regulated by the social condition and the number of members of the families inhabiting them, with this simple rule, which is applicable to them all,—namely, that in the sleeping apartments, not especially provided with apparatus for producing artificial ventilation, a cubical capacity of not less than 700 feet should be provided for each person. It cannot, however, be too often repeated, that no sleeping room ought to be constructed without some provision for the renewal of the air affected by respiration; and, therefore, if there should be no fireplace in the room, ventilators must be provided. As a general rule, also, no sleeping rooms should be constructed in the roofs of houses, because the materials of which the latter are composed are not usually able to resist the effects of variations of temperature. In the best houses, the kitchens, sculleries, and offices are detached from the living rooms; though in London, and indeed in the majority of English towns, they are commonly placed in the basements, care being taken to prevent the smell of the cookery from pervading the house. Under all circumstances, the water-closets, or other analogous conveniences, must be erected in such parts of the building as to allow of their having free communication with the external air. Wherever basements are used for dwelling purposes, they ought to be constructed so as to leave at least one-third of their height above the ground-line, and to present a clear space in front of the external walls equal at least to the depth of the floor-line from the ground-level. The floor, whether of wood or of

stone, should be laid hollow, and an efficient ventilation be established under it. A clear space, or back yard, equal in area to the house itself, ought to be provided to all town dwellings.

4. The old classification adopted in the metropolis, by which houses were grouped as 1st, 2nd, and 3rd rate houses, presented some advantages, at least for descriptive purposes; and as the minimum dimensions of rooms adapted to the respective rates have been settled with a tolerable degree of accuracy, they are appended; as memoranda, rather than as rules.

a. The poorer descriptions of 1st rate houses had front sitting-rooms 15 feet wide, by 14 feet long, by 10 feet high; passages, 5 feet wide; well-hole for staircase, 6 feet 2 inches wide; back rooms, 13 feet 9 inches wide, by 14 feet 3 inches long; in all cases clear of walls or partitions of any kind. The basements were made 8 feet clear height; the bed-rooms about 9 feet high.

b. The poorer descriptions of 2nd rate houses had front rooms 13 feet wide, by 13 feet 6 inches long, by 9 feet high; passages, 4 feet 3 inches wide; well-holes 5 feet 4 inches wide: back rooms, 13 feet 6 inches long, by 12 feet 6 inches wide. The basements were made about 7 feet 6 inches high; the bed-rooms from 8 feet to 8 feet 6 inches high.

c. The poorer descriptions of 3rd rate houses were made with front rooms 10 feet 9 inches wide, by 11 feet long, by 8 feet high; lobbies, 3 feet wide leading to staircase, in the middle of the houses, 2 feet 9 inches wide; and back rooms the whole width of the house by about 10 feet 6 inches deep. The bed-rooms were made from 6 feet 6 inches to 7 feet high.

5. It may be as well to add that, in towns, it would be desirable to make the width of alleys (or the passages for foot-passengers only), not less than 15 feet; and to limit the height of the houses to the same dimension, measuring from the ground line to the top of the wall-plate of the roof, when the ridge is parallel to the front; or to the top of the parapet, if the roof be made in the form known as a hipped V roof. When, however, houses face upon streets in a continuous line, the height may be made equal to the clear space between the front walls on the opposite sides; but as in case of fire it is difficult to force water to a greater height than 70 feet, it may be suspected that the above limit (namely, 70 feet), ought to be adopted for private residences. The width of streets, of course, will be regulated by the amount of traffic they are likely to receive, but it may be said to range between 40 and 80 feet, including the footpaths.

HOUSEBREAKING. [LAW, CRIMINAL.]

HOUSE OF CORRECTION. [PRISON.]

HOWITZER, a piece of ordnance which is constructed to throw shot and shell of a large calibre at short ranges. The gun being comparatively very light, the charge of powder is small, and consequently the angle of elevation required is high. It may be considered intermediate between the gun and the mortar; though it is mounted on a gun-carriage. It derives its name from the German word *haüfen*, "to fill." The name perhaps did not at first indicate a distinct species of ordnance, but was applied to any gun filled or charged with slugs or case-shot. Short guns for the discharge of shells were used in Italy in 1618; but they do not appear to have been introduced into France till 1683, about which time they were also adopted in the British service. Howitzers are made of brass and iron; the former forming a portion of field-batteries, the latter of siege-trains and garrison artillery. The brass howitzers are denominated 24-pounders, 12-pounders, 5½-inch, and 4⅖-inch, from the weight of the round shot which they will carry, and the diameters of the shells discharged from them. The iron howitzers are the 8-inch and 10-inch. Their lengths are respectively:—

Iron, 5 feet, and 4 feet.

Brass, 4 feet 9 inches, 3 feet 9 inches, 2 feet 8 inches, and 1 foot 11 inches.

The fire of shells from brass howitzers in the field is found very effective against villages, stockades, palisades, &c. The iron howitzers are used in sieges, principally for RICOCHET.

The modern shell guns [ORDNANCE] are a description of howitzer.

HUE AND CRY was the old common-law process of pursuing with horn and voice all felons and such as had dangerously wounded another.

Though the term has in a great measure fallen into disuse, the process is still recognised by the law of England as a means of arresting felons without the warrant of a justice of the peace. Hue and Cry may be raised either by the precept of a justice of the peace, or by a private person who knows of the felony; who should acquaint the constable of the vill with the circumstances and the person of the felon; though, if the constable is absent, hue and cry may be made without licence. When hue and cry is raised, all persons, as well constables as others, are bound to join in the pursuit and assist in the capture of the felon. A constable also who has a warrant against a felon may follow him by hue and cry into a different county from that in which the warrant was granted, without having the warrant backed. The pursuers are justified in breaking the outer door of the house where the offender actually is, and are not liable to any punishment or suit if it should appear that the hue and cry was improperly raised, but the person raising the hue and cry wantonly and maliciously may be severely punished as a disturber of the public peace.

HUGUENOTS was the name given to the early followers of the Reformed or Calvinist religion in France. The origin of the name has been variously accounted for. It is said to be derived from the German word "Eidgenossen" ("bound together by oath"), which was the name assumed by the confederate cantons of Switzerland, and which was afterwards adopted by those citizens of Geneva who promoted the alliance of that republic with the cantons of Fribourg and Bern, in opposition to the partisans of the duke of Savoy, who were called Mamelucs, that is slaves. The word Eidgenossen, being transferred into the French language, was corrupted first into Eguenots, and lastly Huguenots. (Bérenger, 'Histoire de Genève.') It is also said to have been derived from the early meetings having been held on a heath near Tours, haunted by the ghost of Hugo Capet. When the Reformation began at Geneva, the party which favoured it, being in great measure the same which had supported the Swiss alliance, retained the appellation of Eguenots, or Huguenots, and as several of the early French reformers came from or were connected with Switzerland, and especially with Geneva, the name spread into France, and was applied to the partisans of religious reform during the times of religious war and persecution. The Roman Catholics used the name of Huguenots as a word of reproach against heretics. The word is now obsolete, and has been replaced by that of "Réformés," which is given chiefly to the disciples of Calvin, while the more general name of Protestants includes the Lutherans. The war and persecutions of the Huguenots are matters of history, but a good account of those of the Calvinistic branch has been given by Dr. G. De Félice, in his 'Histoire des Protestants de France depuis l'origine de la Reformation jusqu'au le temp present,' 1850, of which there is more than one Englisht ranslation; 'De l'etat des Protestants en France,' by Aignan, 1818; and Merle d'Aubigné's 'History of the Reformation in the 16th Century,' 1835, &c.

HUMIC ACID. [GEIN.]

HUMIDITY is that property of a substance by which it communicates to a body in contact with it some of a liquid which it may have absorbed; and the term is commonly applied to the atmosphere when it is in a state to deposit moisture upon bodies in it.

The humidity of the atmosphere is caused in a great measure by the evaporation of water from the seas, lakes, &c., of the earth; and the quantity of moisture which a volume of air is capable of containing depends upon the temperature: when the latter is low at any part of the earth's surface, the air may be saturated with moisture so as to be incapable of holding any more, but the quantity of moisture in a given volume will then be small. If the temperature be increased, the atmosphere, becoming thereby comparatively dry, acquires immediately the power of receiving more vapour, and the power increases with the temperature, so that, in a given volume of air, the quantity which consists with the state of saturation is also increased. Whatever be the quantity of vapour which constitutes the state of saturation, if the temperature be suddenly lowered, or if there be presented a body which has an affinity for water, a precipitation of the latter takes place, or water becomes absorbed in the body. [DEW; EVAPORATION; HYGROMETRY; RAIN.]

The temperature of the atmosphere over any place on the surface of the earth diminishes as the distance of the stratum of air from the surface increases: the power of the air to hold vapour diminishes accordingly; and, as a general law, it may be stated that the humidity of the atmosphere decreases from the surface of the earth upwards. The great dryness of the atmosphere near the summits of mountains has been frequently remarked by travellers, but the quantity of moisture in the different strata is, from local influences, subject to many irregularites. The temperature of the lower strata of the atmosphere diminishing as the latitudes of places on the earth increase, a given volume of air, as a cubic foot, when completely saturated, will contain less water as a station is farther from the equator; and the like may be said of the entire column of the atmosphere over a station. This may serve to account for the fact that, in general, the weather becomes fine when the mercury rises in the tube of a barometer; for then, by the increased density of the air, the clouds are made to ascend in the atmosphere to a region where, the dryness being great, they are readily dissipated. On the contrary, when the mercurial column diminishes in length, the clouds descend; and arriving near the earth, they enter a region in which the atmosphere is at or near the state of saturation; when, consequently, the vapours are easily precipitated. Biot observes, on this subject, that the descent of the mercury is a more certain prognostication of rain than its ascent is of fair weather; the ascent of the clouds in consequence of an increased density of the air not being necessarily accompanied by their dispersion. From the agitation produced by high winds, the upper regions of the atmosphere are often charged with aqueous vapour; and rain may then fall while the top of the column of mercury is above its mean height, and even while it is rising in the tube.

The atmosphere often becomes humid from the evaporation of liquids by artificial means. In establishments for brewing, dyeing, and the like processes, the vapours produced from liquids which are constantly in a state of ebullition rise in the atmosphere, and even render it opaque. The breathing of men and animals produces a watery vapour which renders the atmosphere humid; and when a number of persons are assembled in a close apartment the humidity is sometimes so great that water flows down the walls. The leaves of plants also discharge, in the form of vapour, the water which is imbibed by the roots; and in conservatories this effect is particularly sensible.

In order to determine the quantity of water which is contained in earth when completely saturated with rain, Dr. Dalton took a quantity of garden mould, on which rain had fallen copiously during the preceding day, and exposed it to different degrees of heat. When it seemed to have about the same degree of moisture as soil at the depth of two inches from the surface in dry summer weather, he weighed it, and found that it had lost one-twelfth of its weight; and when it had lost two-ninths of its weight it seemed like the upper soil in summer. His conclusion is that a body of earth one foot in depth, when saturated with moisture, contains seven inches in depth of water, and that it may lose one-fourth or one-half of that quantity without becoming incapable of supporting vegetation.

The effects of humidity on the dimensions of bodies are various: when a watery vapour penetrates between the twisted fibres of cordage, which are vegetable materials, the cordage swells out transversely, and thus becomes shortened; while cords made of animal substances become relaxed by humidity and increase in length. Most salts absorb water, and thereby increase in weight.

HUMIN. [Gein.]

HUMOPIC ACID. [Humopinic Acid.]

HUMOPINIC ACID ($C_{48}H_{23}O_{17}$, or $C_{40}H_{20}O_{14}$?). *Humopic Acid.* A product of the decomposition by heat of narcotine, which on being melted and exposed to a temperature of 428° is suddenly decomposed, with considerable intumescence, into ammonia and a brown vesicular substance, which consists chiefly of the acid in question.

This acid is a dark brown amorphous body, which melts on exposure to heat, and burns with a bright flame, diffusing an odour resembling that of narcotine. It is soluble in water, dilute acids, and in alcohol, giving with the latter a deep red-coloured solution. With the alkalies it forms saffron-yellow coloured solutions, which give dark brown precipitates with the salts of baryta and lead. When humopinic acid is boiled for some length of time in water, it becomes insoluble in ammonia, and, when added to potash or alcohol, a blackish brown substance remains undissolved, which is probably humin. Its composition has not been determined with certainty.

HUMULUS LUPULUS, MEDICAL PROPERTIES OF. [Hops.]

HUMUS. [Gein.]

HUNDRED. [Shire.]

HUNDRED COURT. [Courts.]

HUNDREDWEIGHT. [Avoirdupois; Weights and Measures.]

HUNS, HUNNI, the name given by historians to several nomadic Scythian tribes, which devastated the Roman empire in the 5th century. It appears that these people inhabited the plains of Tartary near the borders of the Chinese empire for several centuries before our era, and that they were known to the Chinese by the name of Hiong-nu, and also Han. They made many incursions into China, and it was to put a stop to them that the Chinese built their great wall, about two centuries B.C. In after-times they became divided into the Northern and Southern Huns. The Northern Huns, being defeated by the Chinese about A.D. 93, emigrated westward as far as the Volga, where they met the Alanni, or Alani, another powerful Scythian tribe, which they routed and drove beyond the Tanais, or Don. The Huns then encamped in the plains between the Volga and the Tanais, and as far south as the ridge of the Caucasus, where they remained for more than two centuries. Under the emperor Valens, they first crossed the Cimmerian Bosporus, drove before them the Ostrogoths and Visigoths, and obliged the latter to cross the Danube, when the emperor granted them lands in Thrace. The Huns were joined by numerous other Scythian hordes, and were looked upon with equal dread by the Gothic and Teutonic nations and by the Romans. Their features and general appearance are described by the Roman historians as hideous and repulsive, and their manners as savage in the extreme. ('Ammianus,' b. 31.) The description of their features seems to correspond in some degree with that of the Calmucks of the present day. The Huns being now on the frontiers of the empire, had frequent wars with the Romans, and their incursions were dreadful though not lasting. [Attila, in Biog. Div.] After the death of Attila the various tribes under his sway quarrelled among themselves, and being attacked by the Goths they were driven back beyond the Tanais. Part of them settled in Pannonia, to which they gave the name of Hungary, but the present Hungarians, or Magyars, come from a different and much later immigration. The Huns are mentioned in subsequent history as being sometimes at war with the emperors of Constantinople, and at times as their allies against the Persians. Under Heraclius many of the Huns embraced Christianity. After that period their name is no longer mentioned in history. (Des Guignes, 'Histoire des Huns.')

HURIN. An acrid non-azotised crystallisable substance obtained from the juice of the *Hura crepitans.*

HUSBAND. [Divorce; Separation, Judicial; Wife.]

HUSBANDRY. The origin of the simplest arts of life is involved in the obscurity which envelopes the early history of the human race. Before there can be any motives to record events, some considerable progress must have been made in civilisation. When attention is altogether directed to obtaining the means of subsistence, there is little leisure; nor is there any great desire to communicate the knowledge acquired by experience. Warlike achievements are the first things recorded; and the peaceful labours of the husbandman are overlooked. In the fables which in the early ages of the world supplied the place of authentic histories, some conspicuous character was always made the inventor of the various arts of which the origin was unknown; and to such personage a divine origin was frequently ascribed. Thus Cadmus is said to have invented letters, and Triptolemus to have made the first plough.

In the oldest writings which have been handed down to us, the common operations of husbandry are mentioned, or alluded to, in nearly the same terms in which we should describe them now—the same implements were then in use, and the same productions raised which are now found in the same climates: but they are only mentioned incidentally. It requires a very advanced state of the arts and of literature to produce a treatise on any one practical subject exclusively; and the simpler and more common the arts, the less they are noticed in the early literature of a nation. We have, however, no other means of tracing the progress of husbandry than by the works of those who have written on the subject, until we come to our own times, when everything is noted and commented on, and every one who makes any discovery or improvement is anxious that the public should be acquainted with it. We have already mentioned some of the early Greek authors [Arable-Land], and likewise some of the Latin authors most generally known as having treated of husbandry in general. ('De Re Rustica.') From these authors we learn that considerable progress had been made in the tillage of the ground and in the breeding and rearing of domestic animals: and it appears that wherever the Romans carried their victorious arms, they also introduced improved methods of cultivation. The practice of fallowing land, to restore its fertility, can be clearly traced to them. For a long time the Latin authors were the source from which all writers on husbandry derived their knowledge; and hence many useless and absurd rules, which were connected with the pagan superstition were perpetuated.

The Mediterranean Sea and the countries situated around it were once the centre of all the arts, which had slowly travelled westward from Asia and from Egypt; and the colonies which the Greeks and Romans planted on all the coasts of this sea, and in the countries which they conquered, contributed to diffuse a knowledge of the various products of the earth. The irruption of the barbarians into the Roman empire greatly checked the progress of husbandry; but the destruction of the Eastern empire, while it made the Greeks retrograde in civilisation, tended to introduce improvements into those countries where men of learning and science sought a refuge from the invaders.

British Husbandry.—The husbandry of the aboriginal Britons was probably very imperfect before the invasion of Julius Cæsar; but we have no records to inform us. Rural matters were of too little importance in the eyes of conquerors to engage much of their attention, but the mildness of the climate and the general fertility of the country, induced many of the Romans to settle here; and from them the natives learned a better system of cultivation than that of their ancestors.

As far as we can learn from ancient documents, the land in England formerly consisted chiefly of woods and of extensive pastures, in which sheep and cattle were bred, which constituted the chief wealth. A very small proportion of the soil was cultivated; and while the population was thin, there was no difficulty in obtaining land which had never before been broken up, and which with little trouble or manuring produced moderate crops of corn. But this system could not last long. The proprietors of land would soon perceive that the produce fell off, and would consequently restrict the breaking up of pastures, and thus more attention was necessarily paid to the arable lands in cultivation.

Through the deficiency of the laws, or the difficulty of executing them, and the frequent intestinal wars between the barons, depredations were often committed with impunity; and the cultivators of the soil congregated in villages for mutual protection and defence. The best land nearest to the habitations was cultivated, and the common pastures fed the cattle without much trouble or expense. The consequence of this system was, that very little manure was made, and the cultivated fields scarcely produced a return adequate to the expense of cultivation. Four times the seed was a full average for corn crops, and the land was overrun with weeds after a single crop. Hence it was not an uncommon practice to have a fallow every other year, and this was considered a superior system to having two crops between the fallows, which has been more common since. Wheat was very little cultivated; barley, rye, and oats were the principal produce.

The woods nourished many hogs on the acorns and beechmast which abounded there, and the right of turning hogs into the king's forests was granted under the barbarous terms of *mastagium* and *rootagium.*

The religious orders, to whom extensive grants of waste lands were made, greatly contributed to the improvement of agriculture. The monks, by their knowledge of Latin, were enabled to study the Roman authors on husbandry, and, by applying the rules and principles which they drew from that source, they greatly improved their estates, and made the land more productive: teaching and encouraging their tenants to till the land more effectually, they were, upon the whole, better and more indulgent landlords than the nobles, who, provided they secured retainers and supplied their households with necessaries, gave themselves little trouble about anything else. Bread made of rye, barley, peas, or beans, was the principal food of the labourers, who were attached to the soil, and had no right to remove to another place or serve any other master. The immediate tenants of the lord of the soil cultivated a portion of the lands which they held for their own use, and let the remainder to smaller tenants, who, although born free, were little above the condition of the labourers, and lived much in the same manner. There was so little capital among the farmers, that the live stock was frequently the property of the landlord, and was let with the land, as well as the servants. As to implements, they were very few in number, and rudely made by the farmer himself; an iron plough-share, an axe, and a spade, were the principal instruments for which he had to pay.

Oxen, which could be kept on the common pastures at little expense, were used for the plough; and so badly fed were they in general, that it required six oxen to draw a plough, which barely turned up half an acre in a summer's day. These oxen consumed all the straw of the farm in winter, and little was left to make manure of. Horses carried the corn to the mill or market on their backs, the roads being mostly impassable for wheel-carriages, which indeed were unknown in many parts of the country.

These particulars can only be gleaned out of various authors, who incidentally mention the state of the agricultural population, and from ancient deeds and documents.

With the revival of letters, and especially with the invention of the art of printing, greater attention began to be paid to rural affairs: but all the early English or foreign authors who touch on the subject of agriculture took their notions from the Latin writers *De Re Rustica*, and rather say what should be done, than what really was done.

The first English author of any note who wrote on husbandry was Sir Antony Fitzherbert, who has by many been looked upon as the father of English husbandry. He published his 'Book of Husbandrie' in 1523. This work throws considerable light on the state of the farmers in those days, who, with their wives and children, worked hard, and were little raised above the common labourers, except that they were freemen. A yeoman who had land of his own was a very independent man; but his mode of living was extremely plain, and he had no luxuries. Money was seldom seen in his possession. He lived on the produce of his land, and fed his labourers at his own board. Wool was the principal article sold. The sheep were kept on extensive commons, at little expense; and in some places the folding of them on the land was the principal mode of recruiting it when exhausted. The great difficulty was to keep them alive in severe winters, and many perished every year. The only provender they had was hay; and as artificial grasses and turnips were unknown, natural meadows paid an enormous rent, when compared with arable land. For want of winter provender for cattle, many were killed which were not sufficiently fat. Very little fresh meat was eaten after Christmas, and every family had oxen and sheep killed and salted in autumn to last till the next summer.

In the time of Elizabeth some attention began to be paid to the improvement of husbandry, but no works of any note have come down to us in which we can discover that any considerable change was made in the common modes of tillage or in the rearing and feeding of cattle.

The situation of the farmers however appears to have improved: they began to acquire wealth and to increase their domestic comforts. The farm-houses were more solidly built and commodious, having before been chiefly constructed of wood, and the walls plastered with clay.

Cromwell encouraged husbandry, and gave a pension to Hartlib, who published in 1641 a work on the husbandry of Flanders, and another in 1651, called the 'Legacy of Husbandry.' Walter Bligh, the friend and contemporary of Hartlib, published in 1652 another work called 'The Improver Improved.' This work is deserving of notice. It contains very sound principles of husbandry, with many excellent observations, which may be of great use even in our days. The author mentions clover as an important object of cultivation introduced from the Netherlands; and he may be considered as the first who recommended sowing this plant for feeding cattle. Sir Richard Weston, who soon after gave an account of the cultivation of turnips in Flanders, laid the foundation of the improved system of husbandry, of which the feeding of cattle and sheep on turnips in winter is the chief feature.

From that time till the present day husbandry has improved slowly but regularly. With the increase of population and a consequent increased demand for the produce of the soil, there has arisen a new species of speculation, that of reclaiming waste lands, by which the estates of many landed proprietors have been greatly improved. But the most important step has been the granting of long leases to those who were inclined to lay out their capital and employ their skill in improving farms. The security which the law gives to a leaseholder and his independence of his landlord, provided the rent be duly paid, affords the greatest encouragement to industry; and it will be invariably found that the improvement of any district is proportioned to the length of time for which leases are granted there, at a fair annual rent, without uncertain fines.

The spirit of improvement and the hope of increasing his income often lead a man to mistaken experiments and consequent loss; but the experience thus gained is always valuable to the community. Jethro Tull, a gentleman who had a property near Hungerford in Berkshire, introduced a mode of cultivation which was prevalent in Lombardy, and was borrowed from the practice of gardeners, who sow and plant their vegetables in rows with wide intervals. Finding that in rich soils the produce was much increased by stirring the earth round the roots of plants, he formed a theory respecting the food of plants, which he imagined to be extremely finely attenuated "earth." He thought that manures acted only mechanically, and that by continually stirring the soil it might be kept perpetually fertile. The attractive part of this theory was, that whereas the supply of manure is limited, there is no limit to labour, and that consequently an increase of population only required an increase of tillage to supply it with food. Tull was admired, and his theory adopted by many eminent men. His practical system, to which the name of *drill-husbandry* has been given, was looked upon as one of the most important discoveries. Notwithstanding that his imagination led him too far, he must be considered as one of the great promoters of good husbandry. Even his errors have been useful by making men observe and reflect; and the introduction of machines to drill the seed in rows, and of others to clean and hoe the intervals, which he principally suggested, has been of infinite use to the improved cultivation of the soil.

The rearing and fattening of cattle on the produce of arable land, which followed the introduction of sainfoin, lucern, and other artificial grasses, and the cultivation of roots for the same purpose, have made a great change in the old systems. Manure is produced in greater quantity; the land increases in productive power, and will bear more frequent crops of corn; better implements have been invented to save labour and to do the work more completely; and a system of draining has been introduced, which has corrected the great fault of most strong soils in northern climates—excessive moisture, which cannot evaporate. Many causes have concurred to produce these improvements. At one time high prices induced men to lay out their capital on the cultivation of the soil; at another, low prices stimulated industry to make up by an increased production for a deficiency in the value; and what has contributed greatly to keep attention directed towards agricultural improvements is, the rapid increase of the means of communicating information by the press. Every successful experiment, every new method which the inventor thinks of importance, is speedily announced to the public.

The improvements which have been made in the breeds of cattle and sheep may be considered as entirely modern. The profit which some eminent breeders have made, and, to some extent, still make, by their attention and their skill, is a sufficient inducement to excite competition. Mr. Collins and Mr. Bakewell may be cited as examples of successful attention to breeding. Mr. Collins obtained at a public sale of his cattle—

For 17 cows of all ages	£2669
For 11 bulls	2249
For 7 bull-calves under one year old . . .	655
For 7 heifers	808
For 5 heifer-calves under one year . . .	306
Making for 47 head of cattle of all ages . .	£6687

And such prices have been, since his time, of late years rivalled by the sales of well-bred stock.

To enumerate the various works which have come from the press on subjects connected with husbandry would be to give a catalogue of a large library. We can only mention some of the principal authors, such as Lord Kames, Marshall, Arthur Young, Sir John Sinclair, and Dickson. Of these, the most original author is perhaps the first. But the works of Arthur Young are those which afford the fullest information on the state of British husbandry in the latter half of the 18th century, and did most towards its general improvement. The 'Farmer's Magazine,' which appeared in 1800, and continues under a new set of editors to this day, has done much good in disseminating useful practices in husbandry. British husbandry owes much to the zeal and activity of individuals who have formed societies for its improvement. The Bath and West of England Society, which still exists, and has of late years greatly extended its operations, has been very instrumental in spreading the knowledge of practical husbandry, and much useful information is contained in the Reports of its Transactions. The Highland Society of Scotland, of which all the principal proprietors and most of the large occupiers of land in Scotland are members, has greatly contributed to encourage experiments, and to promote improvements in every branch of husbandry.

The Board of Agriculture, at the head of which was Sir John Sinclair, the zealous promoter of all measures for diffusing agricultural information, although it rather disappointed the hopes and expectations formed at its commencement, and has for some time ceased to exist, was the means of diffusing a knowledge of the state of husbandry throughout Britain, at the beginning of this century, by the publication of the Agricultural Surveys of the different counties, the substance of which was condensed in the 'British Husbandry,' in 2 vols., published under the superintendence of the Society for the Diffusion of Useful Knowledge. The English Agricultural Society, and the other national agricultural associations, have also been influential in giving a new stimulus to the improvement of British husbandry.

To complete this short sketch of British husbandry, it only remains briefly to mention the different systems which have been most prevalent at different times.

The first and most inartificial is that which consists in breaking up portions of pasture-land and sowing corn on a slight ploughing, which cannot fail to be productive for some time. Several crops may thus be taken, until the land is so exhausted, that the crop no longer repays the seed and labour. To defer this time, experience soon pointed out the crops which succeeded best after each other. Wheat or barley were probably the first crops; afterwards peas, beans, or oats, until the ground, being overrun with weeds, would be left to the renovating effect of time, and a fresh spot would be broken up.

The first improvement on this system is that of infield and outfield. The infield is cultivated more carefully, somewhat like a garden, and all the dung of the cattle is exclusively put upon this part. The outfield is a continuation of the first-mentioned system. The infield consisted of inclosures or open fields near the dwelling, which it was most convenient to cultivate as arable land. Thus two distinct systems of husbandry were carried on at the same time; and whatever improvements were introduced in the management of the infield, the outfield continued to be managed as it was before.

The mode of recruiting by means of a fallow lands which had been exhausted by crops, or were overrun with weeds, seems to have been introduced into England by the Romans; but appears not to have been practised in Scotland till the 18th century. The differences in Scotland of the mode of tenure from that of England, and the little peaceful intercourse of the two countries, may perhaps in some degree account for the non-adoption of the summer-fallow. The alternate crop and fallow seem to have been later introduced than a fallow after several crops. The triennial system, which consists of a summer fallow, a winter crop, and a spring crop, was probably longer established than any other, and is still the practice in many parts of England. The deteriorating effect of the outfield system would lead to its abandonment as soon as population increased, and with it the want of land for infield. The common-field lands, which were so extensive till within the last fifty years, many of which have since been inclosed by special acts of parliament, were probably at first only portions of commons, which were broken up by common consent, and formed into outfields. The right of pasture over them, after the crops are removed, strengthens this supposition.

When common-fields are divided and inclosed, a better system of husbandry generally follows. Clover and turnips are more regularly sown, and, on light lands, take the place of summer fallow. Clover generally comes after a crop of corn, in which it was sown the preceding year in spring; and as most crops succeed well after clover, wheat was usually chosen for the next crop as the most profitable. Thus arose the Norfolk system, without any very sudden departure from the old rotations. Two crops raised for the food of animals in four years require more cattle on the farm to expend them profitably: and thus more manure is made. In the light soils the sheep when folded on the turnips not only enrich the land by their dung and urine, but likewise render it more compact by treading it, which is advantageous to the clover and wheat which come after. If the land is a good loam, beans are sometimes sown after wheat, the land having been recruited with manure; and if the beans are kept clean by hoeing another good crop of wheat may be obtained after them. Thus arises the improved rotation of turnips, barley, clover, wheat, beans, wheat; after which the land is again cleaned and prepared for turnips with all the manure that can be spared. As in this system there is always a crop with succulent leaves intervening between two which have a white straw, it has been called the *alternate* system of husbandry. These are the most common systems in England. The removal of the fallow year, provided the land be kept clean, is a decided step towards improvement. The best farmers effect this by the introduction of artificial grasses and tares fed off by sheep, and especially by sowing every crop in rows and keeping the intervals stirred, which is a partial fallow without losing a crop. Here Tull's system is introduced, which in its complete state, as the author recommended it, was soon abandoned.

As the English systems have taken their origin chiefly from the infield cultivation, so the Scotch appear to have arisen from that of the outfield. Fallows were unknown; but the invigorating effect of grass fed off by cattle must soon have been perceived; and instead of leaving the land to recover slowly by the spontaneous growth of natural herbage, which on poor land takes a long time, it was obvious that this might be accelerated by sowing grass-seeds. Hence the origin of the Scotch convertible system of husbandry, which is gaining ground daily, and bids fair, in remote situations where no manure can be purchased, to be firmly established. The order of the conversion has been somewhat altered from what it was originally. Instead of sowing grass-seeds after the land is exhausted, it has been found advantageous to accelerate the growth of grass by manuring the crop in which it is sown; and experience has proved, that the richer the grass is, the more productive are the crops which come after. The grass, instead of being a mere substitute for fallowing and manuring, is made highly profitable by feeding cattle and sheep; and the profit of the years when the land rests, as it were, by being depastured, is often as great as that of the years when it is cropped; and the risk and expenses are much less. The convertible system is not very generally known or adopted in England, and is often confounded with the alternate system. The alternate system interposes a green crop between two white-straw crops. On good land the convertible husbandry may consist of three or four years' tillage and three years' grass. If the land is not quite clean, a summer fallow on heavy soils, or a turnip fallow on light soils, should begin the course; and only one crop should be taken after the fallow in which the grasses are sown, whether it be wheat, rye, barley, or oats. It should be fed off the first year, mown the second, and fed off again in the third; when it is broken up, oats are usually sown as the first crop in Scotland, then beans, if the land admits of them, and then wheat. If a fallow is intended, a crop of peas may be sown after the wheat, and then the course begins again, as before, with a clean fallow or with turnips. In this manner the land may be kept clean, and continually improve in fertility by means of the cattle which are kept upon it, without the aid of any purchased manure, except lime, the expense of which is in most cases well repaid by the crop. These are the only regular systems in Britain; and every mode of cultivation and cropping may be reduced to one of them, unless it be capriciously anomalous. Of late years Tull's husbandry, applied to the perpetual succession of wheat crops on the same land, has been developed and somewhat modified; and, now known as the Lois Weedon system, has been pretty extensively tried. The Rev. S. Smith, of Lois Weedon, has the merit of having thus recalled the maxims and experiments of Jethro Tull to the favourable notice of English agriculturists.

What renders the improved systems of British husbandry so superior to that of all other nations is the attention paid to the perfection of the different breeds of domestic animals, especially the horse, the ox, and the sheep. In this respect British husbandry surpasses every other. No expense or trouble is spared to improve the qualities of cattle and sheep. It has been objected, that the rewards given by different societies for excessively fat cattle are not judicious, as these animals are never profitable to the feeder. The same might be said of very high-bred racehorses; they are not so useful as a good hackney or hunter; but unless some individual animals possess the power, courage, and speed which is the mark of the best blood, it would soon degenerate; so likewise if some oxen were not occasionally fatted to an extraordinary degree, the fatting qualities of the breed could not be proved. A badly bred ox will never become so fat, whatever food may be given him, as one of a choice breed. This the breeders are well aware of, and never hesitate to pay a good price for a young bull of any prize breed.

The great variety of new instruments which are daily invented, and some of which gradually come into use, however expensive they may appear, is another feature in British husbandry; and the letting out of drills and steam threshing machines, which are kept for profit by men who have little or no land to cultivate, is a step to that division of labour which has done such wonders in manufacturing industry, and which will no doubt in time do the same in the operations of husbandry. There is a fresh spirit of improvement arising among practical agriculturists, and not the least favourable symptom is, that it begins to be acknowledged that "much may yet be learned," and that "husbandry is still comparatively in its infancy." The success at length of the reaping machine and of the steam plough is the crowning point of its progress hitherto; and this, conjoined with the extraordinarily developed trade in artificial and manufactured manures, is what indicates most perfectly the energy and enterprise of English agriculturists.

Husbandry in Italy.—It might be expected that Italy would present some remains of the Roman husbandry, but such has been the pernicious effect of wars and intestine commotions, that this fine country, with all the advantages of soil and climate, is far behind less favoured regions in the cultivation of the soil and the rearing of cattle. The plains of Lombardy alone are an exception; but the cultivation of maize, the principal produce there, partakes more of the garden husbandry than that of any other grain. The abundance of water which descends from the Alpine regions fertilises a great extent of soil by artificial channels, in which it is made to disperse itself, and produces a vegetation which requires little assistance, except that of weeding. Italy was however the country where, on the revival of letters, the first books were published on the practice of husbandry. Pietro di Crescenti, a citizen of Bologna, born in 1230, after thirty years' experience in all parts of Italy, wrote a treatise entitled 'Opus Ruralium Commodorum,' printed in 1474. There is a doubt whether it was first written in Latin or Italian, but it was soon translated into French and German. The author quotes Cato, Varro, and Palladius, but not Columella, who probably was not then generally known, or perhaps his works had not yet been rescued from the libraries in which ancient works were long buried. In the succeeding century many of the Greek and Latin authors on husbandry were translated and published. Tavello, in his 'Recordo d'Agricoltura,' 1561, ascribes the deterioration of agriculture to the practice of letting land for three years only, which had been introduced very generally, and perpetuated the triennial system in its worst form. Johannes Baptista Porta, in 1592, published his 'Villæ,' in 12 books, a work which has had a considerable reputation, and is considered by many as still well worth consulting. A variety of authors on different parts of husbandry wrote about this time, in consequence of the frequent famines which arose in Italy from a very imperfect state of husbandry. The 'Vinti Giornate dell' Agricoltura,' Venetia, 1569, which had been first published in 1550, under the title of 'Deci Giornate,' went through more than twenty editions in Italy, besides being often translated. The author ridiculed the foolish astrological notions prevalent at the time, and his work is full of good sense. But all these writers had little influence on the improvement of the actual practice of husbandry in Italy. If a spirited proprietor attempted to introduce improvements, the prejudices and obstinacy of the country people soon disheartened him, and to this day the systems adopted are extremely defective, if there be any system at all. In many places the ploughman still stands on the heel of the plough to keep it in the ground, and a straight furrow is not thought of. The earth is scratched rather than tilled; and if good crops arise from the natural fertility of the soil, they are generally choked with weeds before harvest.

An attempt had been made by Leo X. to drain the Pontine marshes, and it was renewed in 1586 by Sextus V. Pius VI. spent great sums on the same object; but to this day little has been effected; and instead of the fertile plain which once was covered with a golden harvest, there is nothing but a dreary marsh producing pestilential vapours pregnant with disease. Sicily and Sardinia, once the granaries of Rome, now produce only a very small quantity of corn. The best cultivated districts in Italy are Piedmont, Lombardy, Tuscany, and the country about Ferrara; but, except in the two first, they are behind the greater part of Europe in the management of a farm. The proprietor of the land, if he does not cultivate it by his own servants, is usually the proprietor of all the live stock and implements of the farm.

Husbandry of Spain.—Spain possesses a considerable extent of fruitful soil, and the husbandry of the Romans, which the irruption of the barbarians had interrupted, was in some measure revived by the Moors. When they were expelled, Spain lost many industrious husbandmen and manufacturers. A work on husbandry by a Moor, called Ebd-el-awam, who is supposed to have lived about the 13th century, was published with a Spanish translation at Madrid in 1802, and does credit to the agricultural knowledge of the author. The cultivation of the sugar-cane and of saffron are mentioned in this work.

Herrera, who wrote on husbandry at the desire of Cardinal Ximenes, is one of the most esteemed authors of his time. His works have been frequently republished; and are now in great reputation, and looked upon as quite classical in agricultural literature. He laments that mules are generally used in Spain for the plough and other purposes of husbandry, instead of the ox. But Herrera did not succeed in changing the custom; and mules are still in general use. The great object of attention in Spain is the production of fine wool; and the privileges given to the Mesta, a kind of corporation of shepherds, tend greatly to retard the introduction of a better cultivation. The Merino breed of sheep is said to have been imported originally from Britain. But it is evident that, if it is necessary to its perfection that the flocks should run over half the kingdom every year, the profit made by the exportation of fine wool is dearly purchased by the disadvantages of a miserable state of agriculture. Instead of, as from the character of the country she ought, producing a superabundance of grain and supplying other countries, Spain is obliged frequently to import corn in order to prevent a scarcity. The state of Portugal is not better, and the vine is the only plant of which the cultivation is moderately well understood in the whole of the peninsula.

Husbandry of Germany.—The husbandry of Germany varies greatly in such an extent of country. In the time of Tacitus half the country was covered with impenetrable woods. As population extended the forests were cut down, and the sickle succeeded to the axe. The republic of the Swiss cantons and the Hanseatic towns gave the first examples of encouragement to husbandry. In 1571 the work of Heresbach, entitled 'Rei Rusticæ,' libri iv., was reprinted at Cologne. Heresbach was born in the duchy of Cleves in 1509, and is considered the father of husbandry in Germany.

Augustus I., elector of Saxony, wrote a treatise on the cultivation of the vine, which was published in 1636, entitled 'Churfürsten's Augusti zu Sachsen Obstgartenbuchlein.'

In Prussia, Mecklenburg, and Holstein, husbandry has made the greatest progress in modern times. The Prussian government, from the time of Frederick the Great, has taken agriculture under its especial protection. In Prussia there are several schools of agriculture, where this art is taught on scientific principles, and where the practice is shown on large farms. That of Mögelin, over which A. Thaer presided, became conspicuous from the excellent work on rational husbandry, 'Rationellen Landwirthschaft,' which he published. The introduction of the Dutch system of dairying in Holstein, and the breeding of fine horses there, has given a reputation to this part of the Danish dominions. In Bavaria, along the banks of the Rhine, from Basel to Darmstadt, there is a fine fertile plain which is cultivated with some care; and although subjected generally to the triennial system (which is called in England the three-course shift), the husbandry of that part of Germany is not to be despised. In Switzerland the management of grass-lands and water-meadows is carried to great perfection. The cultivation of lucern and sainfoin is very general; potatoes are raised to a very considerable amount; and the soiling of cattle in the stables is universal. The scientific writers of Geneva have contributed greatly to throw light on the theory of vegetation; and it is scarcely necessary to mention Theodore de Saussure, Pictet, De Candolle, and Macaire, as men who have contributed more than any others to explain the functions of vegetable life.

As a practical promoter of husbandry, we cannot pass over M. de Fellenberg at Hofwyl, near Bern. On an estate of about 300 acres he put in practice nearly all that has been written by the most esteemed writers, taking Thaer as his text-book, and making himself acquainted with the best modern writers. He established an agricultural school for poor children, as a part of his great plan for general education, and his example has perhaps done more to promote good practical husbandry in his native country than all the works of the most eminent writers.

Belgium has always been foremost among agricultural countries. In 1600 the Flemings were considered the best husbandmen in Europe. There are no early writers on husbandry in this agricultural nation, but all travellers bear witness to their industry and to the perfection of their agriculture. They were probably the first in modern times who cultivated turnips in the field to feed cattle in winter; and who, in the north of Europe, kept their cattle in the stables all the year round and cut green food for them, as had been done from time immemorial in southern climates, on account of the excessive heat of the day and the annoyance of flies. The Belgians are now far advanced beyond most other nations of Europe in the application and economy of manure. They fully make up by incessant attention and indefatigable industry for the inferiority of their climate to that of Italy or Spain, and their land produces abundantly every necessary of life.

Husbandry of France.—France has always been looked upon as a country peculiarly agricultural. The climate, partaking of that of the north and the south, favours the cultivation of plants both of the warmer and of the colder regions. Charles Estienne is the first French writer on agricultural subjects whose works were published soon after the revival of letters; but, together with many useful maxims which he has copied from the ancient authors, he has repeated the most absurd superstitions. His works were collected and published in 1554, under the title of 'Prædium Rusticum;' and in 1565 he published his work called 'L'Agriculture et la Maison Rustique.' This work was reprinted, with additions, by his son-in-law, Jean Libeaut, in 1570. But the author, who is still considered as the father of French husbandry, is Olivier de Serres, a gentleman of fortune, proprietor of the seigneurie of Pradel, near Villeneuve de Berg, in Languedoc. He was a friend of Sully, the favourite minister of Henry IV.; and, at his request, about the year 1600, he wrote a work on husbandry, under the title of 'Théâtre d'Agriculture et Mesnage des Champs,' a work in which he shows a thorough knowledge of the great principles of husbandry. Subsequent writers on agriculture have been far too numerous to specify. Until recently, however, their influence was extremely small. But of late years a great amelioration has taken place, and the desire to promote practical improvements in husbandry appears to be steadily gaining ground, though the culture of a large part of the country is still in a very backward state. Agricultural schools and veterinary colleges have been multiplied; model farms on a very extensive scale have been established in many places by the Government, and by wealthy proprietors of land; extensive reclamations have been made of waste lands; better modes of cultivation are widely adopted, and the corn-produce has largely increased, partly in consequence of the abolition of the corn-laws in England, which has led the French farmer to look to the advantages offered by new foreign markets, but partly also as a result of the increased facilities offered by the construction of railways for reaching distant home markets. Much greater attention has also been paid of late years to improving the native breeds of stock; and a better class of agricultural implements is gradually coming into use.

HYACINTH, a favourite flower in gardens, is the *Hyacinthus orientalis* of botanists, a bulbous plant, found wild on the mountains of Persia, and remarkable both for its fragrance and the facility with which it varies in the colour, size, and construction of its flowers when raised from seed.

Few spring flowers are more worthy of cultivation than the hyacinth, whether we regard its varied shades of rich colour or the sweetness of its perfume. The Dutch gardeners have been celebrated for the high state of perfection to which they grow it, and for the monopoly they have secured in the sale of the bulbs, which have even acquired in the shops the familiar name of Dutch roots. The soil and climate of Holland seem to be peculiarly adapted to the plant, for however well imported roots may flower in England for the first season, they soon degenerate and become worthless. It is however probable that this arises from want of skill in our cultivation, rather than from anything unfavourable in our climate: for some gardeners have been successful in growing the same roots for several years in succession. Mr. Herbert says, "I produced for several years successively, at my villa in Surrey, where I had the advantage of the vicinity of the fine sand of Shirley Common, hyacinth flowers fully equal, if not superior, to those obtained from the best Dutch bulbs." As experience is in all respects the surest guide, the more nearly we approach the Dutch method of cultivation, the more likely we are to be successful. According to Mr. Herbert, the compost used at Haarlem is rotton cow-dung, rotten leaves, and fine sand. In making this compost the Dutch gardeners prefer the softer leaves of elm, lime, and birch, and reject those of oak, chesnut, walnut, beech, plane, &c., which do not rot so quickly. The cow-dung which they use is also of a peculiar quality, being collected in the winter when the cattle are stall-fed upon dry food, without any mixture of straw or other litter. The sand is procured in the neighbourhood of Haarlem, where the soil is a deposit of sea-sand upon a compact layer of hard undecayed timber, the remains of an ancient forest which has been overwhelmed by the sea. Having all these substances in a proper state, they are prepared in the following manner:—First, a layer of sand is placed, then one of dung, and then one of rotten leaves, each being eight or ten inches thick. These layers are repeated till the heap is six or seven feet high, a layer of dung being uppermost, sprinkled over with a little sand to prevent the too powerful action of the sun upon it. After the heap has lain for six months or more it is mixed, and thrown up afresh, in which state it remains some weeks, to settle, before it is carried into the flower beds. ('Hort. Trans.,' vol. iv., p. 163.)

The bed into which this compost is to be put must be taken out to the depth of three feet, its bottom made firm, and a few stones thrown into it in order to keep it dry. It must then be raised considerably above the level of the surrounding soil with the compost already prepared. The best season for planting is from October to the beginning of November, and the early sorts planted at this time will begin to show their flowers in the beginning of April.

Hyacinths are sometimes planted in rows or patches, but the most common and best way is to plant them in beds, because a greater mass of bloom is presented at once to the eye, and because it is easier to protect and shade them in this way. In planting them in beds a great part of the effect is produced by a judicious arrangement. The different colours are either blended together in the bed, or collected into masses. A mass of one colour is more pleasing to the eye than a mixture of several, and therefore each tint should be planted by itself in the bed; or if there are more beds than one, the first may be planted with white, the second with blue, the third with red varieties, and so on. The distance between each plant should be eight or nine inches.

As hyacinths are planted in autumn, and bloom early in the season, they never require any water. Against sharp frosts protection should be afforded by a covering of fern or leaves. In the spring the soil should be stirred lightly without damaging the bulbs; and a covering of matting supported on arched sticks should be used to protect them on frosty nights, which frequently occur. The bulbs will generally commence flowering in April and continue through May. As soon as the flowering is over, the more dry the ground can be kept, the better it is for the bulbs. When the leaves turn yellow and are withered, which will take place in about a month after the plants have gone out of flower, the bulbs must be carefully taken up and dried. The practice at Haarlem is this. "The leaves should be cut off, and each bulb laid on its side, covering it lightly with the compost, about two inches thick: in this state it should be left about a month, and then taken up in dry weather and exposed to the open air for some hours, but not to a powerful sun, which would be very injurious to it; it should after this be carefully examined, and all the decayed parts removed; afterwards it should be laid up in an airy storeroom." (Herbert, 'Hort. Trans.') Florists who have a valuable bed of hyacinths generally use an awning of some kind, to shade them from a bright sun, and protect them from heavy rains. This shade, of whatever material it is made, should be so constructed as to move up and down in favourable weather; in bright sunshine the bed may be exposed from four o'clock in the afternoon, or for a few hours in the morning. If the bed is not shaded, the colours very soon spoil, and will not bear a close examination.

Forcing of hyacinths is carried to a considerable extent, both in England and also on the Continent. When they are bloomed in this way, they are either used as ornaments to the greenhouse, or placed in the lobby or drawing-room, where the sweetness of their perfume renders them general favourites. The method of forcing them is the following:—Good Dutch bulbs, which are annually imported, are selected for this purpose. To save trouble, all which are intended to be forced may be potted at the same time, and placed in a cool greenhouse or frame; then as many as are intended to bloom at once must be placed in a gentle heat; when their flower-stems appear, others can be brought in which will succeed them, and by going on in this way a regular succession will be kept up. The pots into which they are put need not be large, but should be rather deep. The soil used for potting may either be the same as is recommended above, or a good loam will answer equally well. In potting, the bulbs must not be firmly pressed into the soil, but lie rather loose, and be only about half covered with it.

Hyacinths are frequently grown and flowered in water-glasses; for this purpose they are placed over water in October and November, and they flower in February. Sometimes before they are put into the glasses they are planted in pots, and when the roots have grown a little they are taken up and washed, and placed in the glasses, or they are placed in the glasses at first. The water must be frequently renewed, or it will soon become fetid and offensive. By far the most curious system of treating forced hyacinths is to invert them in large glass jars filled with water. This must be done when the flowers are nearly expanded; and by placing one above the glass, of the same size and colour with the inverted one, the latter presents an appearance of being the reflection of the former. The flowers retain their freshness much longer in the water than when exposed in the common way; but this circumstance, and the curious appearance presented, is all which can recommend the system; of course the fragrance of the hyacinth is in this way entirely lost. The principal difficulty that is experienced by those who force hyacinths in water in sitting rooms is to prevent their growing long, weak, and pale, so as to flower badly, and be in constant danger of upsetting. This is remedied by keeping them close to a window, where they can be constantly exposed to bright light all day long. It may also be added, that in order to secure their pushing out their roots before the leaves lengthen, they should always be kept in the dark for a fortnight or three weeks after they are first placed in the water-glasses, care being taken at that time that the water and the bulbs are not in contact. The moisture that rises into the air will be sufficient to induce the bulbs to put forth roots; and the total absence of light will prevent the leaves from being stimulated into growth.

Varieties are obtained from seed, and particular kinds are propagated by offsets. With the greatest care in gathering the seed, it is very uncertain whether or not the young plants raised from it will turn out well; however, the best sorts to gather seed from are those with strong upright stems, semi-double flowers, and brilliant and distinct colours. The seed must be well ripened, and then sown in good sandy soil, rather lighter than what is recommended for hyacinth compost. The young plants so obtained must not be disturbed or taken up until the end of the second, or, if they are weak, the third year; all that they require during that period is a little top dressing. They may then be taken up and planted in the bed, where they will require the same treatment as old roots; they will flower in the third spring, but it is better to destroy all the flowers of the first season, in order to strengthen the bulbs.

HYADES. [TAURUS.]

HYDANTOIC ACID ($C_8H_8N_4O_8$?). An acid product of the action of concentrated caustic potash upon allantöin. Its existence can scarcely be said to be established.

HYDA'TIDS (*ὑδατίς*, a vesicle, from *ὕδωρ*, water). This name has been applied to various cyst-like productions, which are sometimes found in the bodies of men and animals.

The term hydatid is of the most indefinite application, for under this common denomination are included objects of the most dissimilar nature. In the first place, the term comprehends several species of entozoa, or parasitic animals, which have a distinct independent vitality; secondly, the simple unattached cysts which are frequently met with; and lastly, what have been called false hydatids, which are vesicular bodies, either entirely or partially connected with the tissues by which they are surrounded.

Hartmann in 1686 ('Ephem. Nat. Curios.,' Ann. iv. dec. 2, obs. 73), and Tyson in 1691 ('Philos. Trans.,' No. 193), first clearly observed that many of the bodies, or cyst-like tumours, called hydatids, were distinct living beings, or parasitic animals. They arrived at this conclusion from observing that they had no connection with the organs in which they were found, that some of them distinctly moved when placed in warm water, and were also furnished with projecting processes or heads, having an orifice or mouth at their extremity. Morgagni and others have thought that some of the ancient medical writers, particularly Aretæus and Galen, were acquainted with the true nature of these bodies; but nothing of the kind is clearly stated in their writings, though they often mention the occurrence of hydatids.

The discovery of Hartmann and Tyson was taken little notice of before the time of Linnæus and Pallas, who pursued the investigation; since which time these beings have occupied the attention of many naturalists, among whom may be mentioned Hunter, Müller, Goeze, Cuvier, Laennec, and Rudolphi, who have all admitted the animal existence of the greater part, if not the whole of them. Pallas arranged all the cystic entozoa, except the common globular hydatid, or acephalocyst (which was only considered as a simple serous cyst before the time of Laennec), under the genus "Tænia," on account of the similarity of structure between their mouths and those of the tapeworm. In this classification he was followed by Goëze. Although these views were not generally adopted, it has been recently established by Küchenmeister Von Liebold and others that the various forms of cystic worms are but larval stages of Tænia. [ENTOZOA, NAT. HIST. DIV.]

Hydatids are found principally in the bodies of mammalia; rarely in those of the lower order of animals. They may occur in any part of the body, but are very seldom seen in the mucous cavities and passages, except when they have been discharged into them by the rupture of their containing cyst. This external sac, by which they are mostly surrounded, is generally attached to the tissue of the organ in which it is seated; it is frequently common to many hydatids, but each individual may have a distinct envelope, in the interior of which it floats, and to which it never contracts any adhesion. The fluid which fills the proper cyst of a hydatid is almost always colourless and limpid. The liquid of the common cyst in which they float may present various appearances: sometimes it is quite limpid; at others it may be coloured. When formed in the liver it is often yellow.

The principal forms of cystic entozoa, or true hydatids, recognised by Rudolphi and others are called Cysticercus, Cœnurus, and Echinococcus; to which may be added Acephalocystis. Several species of Cysticercus are enumerated, but the most common are C. tenuicollis, and C. cellulosus. The former (Tænia hydatigena, *Pallas*; Hydatis globosa, *Lamarck*) is met with frequently in the peritoneum and pleura of ruminating animals and pigs. It is often generated in the disease of sheep called the rot, where another entozoon, the "distoma," or fluke-worm, is met with in the ducts of the liver. The C. cellulosus (Tænia cellulosa et T. finna, *Gm.*; Hydatis finna, *Blum.*) is found generally lodged in the tissue of the muscles between the fibres; it occurs sometimes in man, but more frequently in animals, particularly in the hog, where it causes the disease called measles or leprosy. Of the genus Cœnurus (Hydatis polycephalus, *Zeder*), the species C. cerebralis (Tænia vesicularis, *Goëze*; T. cerebralis, *Gom.*; Polycephalus ovinus, *Zeder*) is found in the brain of sheep, oxen, and other ruminating animals. These hydatids occur in various parts of the brain of sheep, but most frequently in one of the lateral ventricles, where they occasion a kind of giddiness, in which the animal turns round and round in one direction; this affection is denominated by the German farmers "das Drehen," by the French "le Tournis," and in England the sheep are said to be "giddy," or to have the "staggers."

Sometimes the hydatid is situated in the fourth ventricle, when it is said to cause a variation in the affection, called in German "das Springen," from the animal springing up. Rudolphi says that he has seen the latter variety occur when one large hydatid has occupied the middle part of the brain. In the first case one-half of the body is rendered partially paralytic from the pressure of the hydatid on the side of the brain, and the opposite muscles by their action turn the body round towards the unaffected side. In the latter form of the disease, Rudolphi says that the equilibrium between the anterior and posterior muscles of the body is destroyed, which causes the animal to spring up. Sometimes two hydatids are found in the same ventricle, and occasionally as many as five or six have been met with. The internal surface of the ventricles is always smooth, and never contracts any adhesion to the cysts. This hydatid is sometimes found as large as a hen's egg; the walls of the bladder are very thin and fibrous; and may be seen clearly to contract. The little worm-like bodies attached to it are scarcely half a line in length, and have the power of retracting themselves within the cyst. These hydatids are most generally met with in yearling cattle and sheep, and their production, or that of the state of health which gives rise to them, seems owing principally to the effects of cold and damp, and watery pasturage, which also occasions the rot in sheep. The best treatment is removal to a dry and sheltered pasturage. In some cases sheep have been cured by the extraction of the hydatids by the operation of trepanning. Whenever any of these forms of hydatids are swallowed by man or the lower animals they proceed to develope themselves into tape-worms.

The hydatids belonging to the genus Echinococcus are commonly called granular hydatids, from the presence of numerous granules or minute particles, which are young hydatids which float in the fluid of the cyst or adhere to its walls. Two species of Echinococcus have been particularly described: one called E. hominis, has been met with in the brain and abdomen of man in a few instances; the other, E. veterinorum, occurs more frequently in the hog and other animals.

The Acephalocyst, or common globular hydatid, to which it is thought by some that the name of hydatid should be restricted, is a simple unattached vesicle, varying in size from a millet-seed to a child's head, filled with pellucid fluid, furnished with no kind of appendix or head, generally associated with numerous others, and contained in a common cyst, which is also filled with fluid. These bodies seem to possess a proper vitality, though dependent for existence on the body of the animal in which they live. They are probably undeveloped or abnormal forms of the more definite species.

Hydatids may be developed slowly, and occasion so little inconvenience, that persons in whom they have been discovered after death may not have suspected disease of the organ in which they existed during life. Occasionally they cause so much irritation that suppuration may take place either around or within the common sac, which may burst externally or into a serous mucous cavity. In either the first or last case the hydatids will be discharged, and the patient may recover; but if the cyst should communicate with a serous cavity, as the peritoneum or pleura, fatal inflammation will occur.

With respect to the treatment for the prevention or removal of hydatids, it is very imperfect. As they generally occur in a cachectic or disordered state of health, those remedies may be given which are most likely to remove that state and improve the general health. When a hydatid cyst is situated so near the surface of the body that it may be easily evacuated, without risk of effusion into the internal serous cavities, it may sometimes be punctured with propriety, which operation will cause obliteration of the sac. (WORMS.)

Pseudo or false hydatids are simple serous cysts or vesicles, either occurring singly or aggregated in clusters, but in both cases having a more or less close connection with the subjacent tissues, from which in fact they grow. The vesicles often found in the choroid plexuses belong to this class; also the cysts which contain the fluid in ovarian dropsy, which may grow to an enormous size. Lastly, one of the most common situations for these false hydatids is in the uterus, where they are described as "vesicles of a round or oval shape, with a narrow stalk to each, by which they adhere on the outside to one another." They may here increase in such numbers as to distend the uterus till it is too large to be contained in the pelvis, and rises into the abdomen. These cysts may be developed in many other situations, and contain fluids of various characters. For further information respecting them we must refer to a paper by Dr. Hodgkin, in 'Med. Chirur. Trans.,' vol. xv., p. 266.

HYDRA (constellation, ὕδρος in Ptolemy), the Water-snake, one of the old constellations. From the time of Aratus downwards it has always been a triple figure: a long snake, represented as trailing upon the ground, bears upon his back a cup (Crater), and nearer to his tail is seated a crow (Corvus). The mythological meaning is altogether unknown.

The great length of this constellation has caused it to be divided into four parts, which are designated as Hydra, Hydra et Crater, Hydra et Corvus, and Hydræ continuatio. The first contains the head and body up to about 10½ hours of right ascension, all near to and south of the bright star Regulus; the second contains the cup and the parts of the body adjacent; the third the crow, with the parts of the body adjacent; and the fourth (beginning at about 13 hours of right ascension) contains the tail. For the third part see CORVUS. In Flamsteed's catalogue Hydra and Hydræ continuatio are treated in all respects as two distinct constellations, with Corvus and Hydra et Crater intervening. Mr. Baily, in his new edition of the catalogue, has treated the two as one constellation, and numbered the stars accordingly, making 1, 2, &c., Hydræ continuationis to be 45, 46, &c., Hydræ.

HYDRACIDS. Acids have been divided into oxacids and hydracids. In the former, an elementary body is combined with oxygen as the supposed acidifying principle; and in the latter, a substance, usually an elementary one, is united with hydrogen as the imaginary acidifying power.

The class of hydracids contains some which have been already treated of, as hydrobromic and hydrochloric acid; others remain to be described. With respect to the general properties of hydracids, it may be remarked that their acidity is in general very strongly marked; that they contain only one equivalent of hydrogen, and that when acted upon by metallic oxides they lose their hydrogen by its combining with the oxygen of the oxide, and the results are water and a haloid salt: thus, to put one of the most familiar cases, when hydrochloric acid is added to soda, or the oxide of sodium, the result is not a hydrochlorate of soda, but chloride of sodium and water. When, however, hydrochloric acid is united to bases which contain no oxygen, then real hydrochlorates are the result: thus, ammonia, which is a powerful alkaline base, combines with hydrochloric acid to form hydrochlorate of ammonia, or sal ammoniac. So, also, when the same acid unites with morphine, or any other oxygenous vegetable alkaloid, it is admitted that the resulting compound is a hydrochlorate of morphine, although this alkaline base and many other vegetable alkaloids do contain oxygen.

Most of the hydracids are gaseous, and are easily combined with water, forming solutions which possess the well known and strongly marked acid properties of sourness, acting upon carbonates, and reddening vegetable blue colours. They are all artificial products, except hydrochloric acid, which is sometimes disengaged from volcanoes.

The usual method of obtaining hydrochloric acid, as well as other hydracids, is that of treating a compound of the radical of the acid and a base with an oxacid and water, that generally used being sulphuric acid. Thus, as already mentioned, hydrochloric acid is obtained by acting upon chloride of sodium with hydrated sulphuric acid; the water suffers decomposition, and its oxygen combines with sodium to form soda, while its hydrogen unites with the chlorine, giving rise to hydrochloric acid; the soda combines with the sulphuric acid to form sulphate of soda. This may be taken as a type of the general action.

HYDRAMIDES. A class of organic compounds which may be described as *diamides*, derived from the action of ammonia upon the aldehydes. Hydrobenzamide may be taken as a type of these bodies; it is formed by acting with ammonia upon oil of bitter almonds:—

$$\underbrace{3\left.\begin{matrix}C_{14}H_5O_2\\ H\end{matrix}\right\}}_{\text{Oil of bitter almonds.}} + 2NH_3 = 6HO + \underbrace{N_2\left\{\begin{matrix}(C_{14}H_5)_2\\ (C_{14}H_5)H\\ H_2\end{matrix}\right.}_{\text{Hydrobenzamide.}}$$

The hydramides are neutral cystallisable substances, insoluble in water, soluble in alcohol, and volatile without decomposition.

The following is a list of the principal hydramides:—

Salhydramide	$C_{42}H_{18}N_2O_6$
Anishydramide	$C_{48}H_{24}N_2O_6$
Cinnhydramide	$C_{54}H_{24}N_2$
Furfuramide	$C_{30}H_{12}N_2O_6$

HYDRANZOTHIN. [CARBAMIC ACID.]

HYDRARGETHYL. [ORGANOMETALLIC BODIES.]

HYDRARGOBENZAMIDE. Synonymous with *Mercury benzamine.* [BENZOIC GROUP. *Benzamide.*]

HYDRATES are compounds of water: the term is however usually restricted to compounds which contain water in definite proportion, which water does not impart regularity of form, or in other words give crystals with the body with which it so unites. Thus when water is added to potash it may form with it either water of solution, water of crystallisation, or water which constitutes it a hydrate. If we take a solution of potash and evaporate it to a certain extent we obtain crystals of potash; heat these and the water of crystallisation is expelled, but no heat whatever is strong enough to expel the whole of the water, and the last remaining portions form with the potash a hydrate, which is a hard substance totally devoid of crystalline form. So also when water is added to lime, a portion dissolves; crystals however of water and lime are obtained with difficulty, but hydrate of lime is the well known dry powder called slacked lime.

It appears therefore, from the above statements, that water of solution has comparatively little affinity for the substance with which it is combined; water of crystallisation has more, but water which constitutes the body a hydrate has the greatest affinity of all.

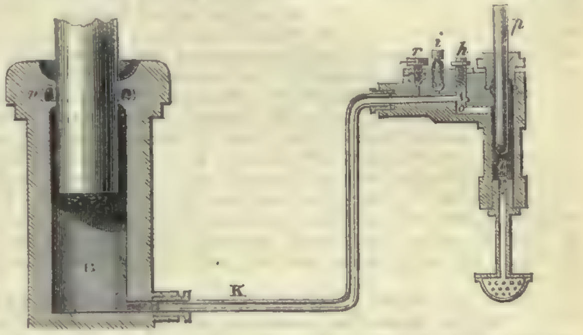
The water with which substances combine often imparts colour to them; thus sulphate of copper when deprived of water is nearly colourless, but when dissolved in water it becomes of a fine blue colour. Water of crystallisation produces the same effect. So also oxide of copper is of a black colour, but the hydrate of oxide of copper obtained by adding potash to a solution of copper is of a beautiful blue colour.

HYDRAULIC ENGINEERING. The branch of the arts of construction which is more especially connected with the resistance to the mechanical action of water, or with the use and application of that fluid to the various purposes of life, is usually known under the name of "hydraulic engineering." The objects comprised under this general title are not only numerous, but they are extremely complicated, and of the highest importance to nations where civilisation has been long and successfully developed. So complicated, indeed, are the objects the hydraulic engineer has to deal with, that there is hardly a branch of the applied sciences he may not from time to time be obliged to enlist in his service; and a mere enumeration of the various leading divisions of his art will suffice to prove the wide range of study it is necessary for him to cultivate. The divisions thus referred to have been, or will be, treated under their respective heads in this Cyclopædia.

The hydraulic engineer, in fact, has to execute the works required for the construction of BRIDGES, especially in so far as the foundations, coffer-dams, &c., are concerned; for BREAKWATERS; CANALS; DOCKS; DRAINAGE; EMBANKMENTS, in water; FOUNTAINS; IRRIGATION; LIGHTHOUSES; PIERS; SEA DEFENCES; SEWERAGE; WATER SUPPLY TO TOWNS; WATER-WHEELS; WELLS; or indeed for any purpose wherein it may be necessary to control or to use water in large bodies. There is little scope for the exercise of taste in these matters; they are nearly all within the domain of exact science; and no doubt their continually increasing importance in our modern societies has contributed to establish the distinction which now prevails between the pursuits of the architect and of the civil engineer; for the latter comprises amongst its varieties that of hydraulic engineering.

HYDRAULIC PRESS. This powerful engine was first suggested by Pascal, based upon the hydrostatic principle of *fluidity*, or the property of transmitting pressure equally and freely in every direction by which a liquid becomes in the truest sense of the term, a *machine.*

The hydraulic press consists essentially of a solid plunger, *p*, working through a water-tight collar in a small cylinder, at the bottom of which is a valve *c*, opening upwards, and conducting by a pipe into a cistern of water. In the side of the small cylinder is a channel, furnished with a valve *o*, opening upwards, and leading by a pipe K into a large cylinder B, in which is inserted a ram, passing through a water-tight collar *n*. The top of this ram is usually furnished with a plate forming the bottom bed of the press, moving in, and surrounded by, suitable frame-work. Now supposing both the cylinders *c* B with the connecting-pipe K to be filled with water, and the plunger *p* to be forced down from the top to the bottom of the small cylinder, the pressure thus produced will be transmitted by the water, through the pipe K to the ram in B, and according to the principle of fluidity [HYDROSTATICS] every square inch of the section of the ram will be pressed upwards with a force equal to the downward pressure on each square inch in the section of the plunger *p*. For example;—if the diameter of the section of the ram be twenty times that of the plunger, the upward pressure of the ram will be 400 times the downward pressure given to the plunger. Of course the pressure on the ram will be communicated to the bottom bed of the press, and any object placed upon it so as to be enclosed between it and the top of the frame will be compressed.



The extent to which the ram rises in the large cylinder must depend upon the relation of its diameter to that of the plunger. The plunger in descending its cylinder, displaces as much water as is equal to the volume of the portion that descends, and this water being driven into the large cylinder B, which is already quite full, the ram must rise through a height sufficient to afford room for the water which is thus forced into the cylinder, and the rise of the ram will clearly be less than the descent of the plunger, in the same proportion in which the sectional area of the plunger is less than that of the ram. If, as already supposed, the section of the ram be 400 times that of the plunger, the ram will rise through the 400th of an inch for every inch of descent made by the plunger. When the plunger is drawn up the cylinder preparatory to another stroke, the valve *c* opens, and admits a quantity of water, equal to the ascent of the plunger. And to prevent the ram from falling during this operation, the valve *o* is placed so as to intercept the water. When the plunger is again driven down, the pressure closes the valve *c* more firmly, and opens *o*. At *r* is a valve closed by a screw, communicating with a pipe that leads to the cistern in which the pump is immersed. When it is required to relieve the ram from pressure, and cause the bed-plate of the press to descend, this valve is opened, the ram descends, and the water from B is driven back through K, and through the pipe by which *r* leads into the cistern. When the press is used for very intense pressures, there is danger of bursting some parts of the machine, so that to prevent the pressure from exceeding a certain quantity, a safety valve *i* is provided. This valve opens outwards, and is closed by a weight attached to the longer arm of a lever, so that when the pressure transmitted to the ram exceeds a certain quantity, the valve opens and relieves the press.

As the pressure communicated to the ram acts with equal intensity on the interior of the large cylinder B, the water which communicates the pressure seeks to escape by the joint or collar through which the ram passes into B. To make such a joint or collar water-tight was the difficulty from the time of Pascal until that of Bramah, who in 1796 took out a patent for a water-tight collar, and thus made the hydraulic press an available engine. The collar is formed of a piece of strong leather in the form of a disc with a hole in the centre, and doubled down at the edges so as to form a ring, with the concavity downwards as shown in section *n*. As this collar exactly fits the ram, the water when pressed upwards enters the concave part, and presses it against the ram on one side and the surface of the cylinder on the other, so as to produce a perfectly water-tight joint, which has the merit of being more completely water-tight as the pressure is increased.

HYDRAULIC RAM. [HYDRODYNAMICS.]

HYDRAULICS. That branch of science which includes the phenomena of fluids in motion, and the modes of obtaining from them useful results. It is usually limited to what are called incompressible fluids or *liquids*, and may relate—1st, to the laws of the effluence of water from a reservoir; 2dly, to running-waters; 3rdly, to the use of water as a motive power; 4thly, to machines for raising water. For the theoretical part of the subject we refer to HYDRODYNAMICS. Its applications will be found under HYDRAULIC PRESS; PUMP; SYPHON; SCREW, ARCHIMEDEAN; WATER-WHEEL; WATER-MACHINE; TURBINE, &c.

HYDRIDES. Compounds containing hydrogen in combination either with an element or a compound radical, but not forming an integral part of a compound radical, are termed *hydrides*. Thus the bodies $(C_2H_3)H$ and AsH_3 are termed respectively hydride of methyl and terhydride of arsenic; but the compound radical methyl (C_2H_3) is not termed a hydride, because in its relations to other bodies it plays the part of a simple or elementary substance. [ORGANIC RADICALS.] The term hydride, as applied to the inorganic compounds of hydrogen, has almost become obsolete, other forms of nomenclature being almost exclusively used for such compounds. Thus we do not call the compounds of hydrogen with sulphur, nitrogen, and chlorine, hydrides, but sulphuretted hydrogen, ammonia, and hydrochloric acid. On the other hand, the term hydride has received very extensive application in naming organic compounds, amongst which we find hydrogen united, in the sense above described, both with positive and negative radicals.

Hydrides of Positive Radicals.—These bodies, isomeric with the positive radicals themselves, constitute an important class of hydrocarbons. They are met with amongst the products of the destructive distillation of organic substances, and can also be formed by two other reactions, namely:—

1st. By heating the potash salts of certain acids with excess of hydrate of potash. In this way hydride of phenyl [BENZOLE] is produced by heating benzoate of potash with hydrate of potash:

$$\underbrace{\left.\begin{matrix}C_{14}H_5O_2\\K\end{matrix}\right\}O_2}_{\text{Benzoate of potash.}} + \underbrace{\left.\begin{matrix}K\\H\end{matrix}\right\}O_2}_{\text{Hydrate of potash.}} = \underbrace{\left.\begin{matrix}C_{12}H_5\\H\end{matrix}\right\}}_{\text{Benzole.}} + 2KOCO_2$$

2nd. The hydrides of the positive radicals are formed by the action of water upon the zinc compounds of the positive radicals, thus:—

$$\underbrace{\left.\begin{matrix}C_2H_3\\Zn\end{matrix}\right\}}_{\text{Zincmethyl.}} + HO = ZnO + \underbrace{\left.\begin{matrix}C_2H_3\\H\end{matrix}\right\}}_{\text{Hydride of methyl.}}$$

The following are the principal known hydrides of positive radicals:—

I. IN THE ETHYL FAMILY.

	Formulæ
Hydride of methyl, or light carburetted hydrogen .	$\left.\begin{matrix}C_2H_3\\H\end{matrix}\right\}$
Hydride of ethyl	$\left.\begin{matrix}C_4H_5\\H\end{matrix}\right\}$
Hydride of amyl	$\left.\begin{matrix}C_{10}H_{11}\\H\end{matrix}\right\}$

II. IN THE PHENYL FAMILY.

Hydride of phenyl, or benzole	$\left.\begin{matrix}C_{12}H_5\\H\end{matrix}\right\}$
Hydride of toluenyl, or toluol	$\left.\begin{matrix}C_{14}H_7\\H\end{matrix}\right\}$
Hydride of cumenyl, or cumol	$\left.\begin{matrix}C_{18}H_{11}\\H\end{matrix}\right\}$
Hydride of cymenyl, or cymol	$\left.\begin{matrix}C_{20}H_{13}\\H\end{matrix}\right\}$

Some hydrides of positive radicals are gases, others liquids or solids. They are remarkable for their stability and resistance to chemical agents. Paraffin probably belongs to this class of organic compounds.

Hydrides of Negative Radicals.—These bodies, commonly termed *aldehydes* (from *alcool dehydrogenatum*), are intermediate between the alcohols and the derived acids, thus:—

$$\underbrace{\left.\begin{matrix}C_4H_5\\H\end{matrix}\right\}O_2}_{\text{Alcohol.}} \qquad \underbrace{\left.\begin{matrix}C_4H_3O_2\\H\end{matrix}\right\}}_{\text{Aldehyde.}} \qquad \underbrace{\left.\begin{matrix}C_4H_3O_2\\H\end{matrix}\right\}O_2}_{\text{Acetic acid.}}$$

They are generally formed by the action of oxidising agents upon the alcohols; œnanthylic aldehyde is obtained by the dry distillation of castor oil, whilst a few others are met with ready formed in essential oils. The hydrides of the negative radicals are as remarkable for their instability as those of the positive are for the opposite property. They rapidly attract oxygen from the air and pass into the corresponding acids; thus, vinic aldehyde passes into acetic acid:—

$$\underbrace{\left.\begin{matrix}C_4H_3O_2\\H\end{matrix}\right\}}_{\text{Aldehyde.}} + O_2 = \underbrace{\left.\begin{matrix}C_4H_3O_2\\H\end{matrix}\right\}O_2}_{\text{Acetic acid.}}$$

They are also very prone to change into isomeric compounds. With the bisulphates of the alkalies they form crystalline compounds. They are powerful reducing agents, throwing down metallic silver when heated with the solution of the ammonio-nitrate of that metal.

The following are some of the chief hydrides of negative radicals:—

I. IN THE ACETIC FAMILY.

	Formulæ.
Hydride of ethyl, or aldehyde	$\left.\begin{matrix}C_4H_3O_2\\H\end{matrix}\right\}$
Hydride of propionyl	$\left.\begin{matrix}C_6H_5O_2\\H\end{matrix}\right\}$
Hydride of butyryl	$\left.\begin{matrix}C_8H_7O_2\\H\end{matrix}\right\}$
Hydride of valeryl	$\left.\begin{matrix}C_{10}H_9O_2\\H\end{matrix}\right\}$
Hydride of œnanthyl	$\left.\begin{matrix}C_{14}H_{13}O_2\\H\end{matrix}\right\}$
Hydride of palmityl	$\left.\begin{matrix}C_{32}H_{31}O_2\\H\end{matrix}\right\}$

II. IN THE ACRYLIC FAMILY.

Hydride of acryl, or acrolein	$\left.\begin{matrix}C_6H_3O_2\\H\end{matrix}\right\}$

III. IN THE BENZOIC FAMILY.

Hydride of benzoyl, or oil of bitter almonds . .	$\left.\begin{matrix}C_{14}H_5O_2\\H\end{matrix}\right\}$
Hydride of cumyl, or cuminol	$\left.\begin{matrix}C_{20}H_{11}O_2\\H\end{matrix}\right\}$

Descriptions of the positive and negative hydrides will be found under the respective radicals.

HYDRINDIN. [INDIGO.]

HYDRIODIC ACID. [IODINE.]

HYDRO. A chemical prefix, see CHEMICAL NOMENCLATURE. *Nomenclature of Acids.*

HYDROBENZAMIDE. [BENZOLONE; HYDRAMIDES.]

HYDROBENZILE $(C_{28}H_{12}O_2)$. A product of the action of sulphide of ammonium upon benzile. It is a colourless crystalline body, soluble in alcohol and ether, insoluble in water, fusing at 117° Fahr., and distilling unchanged. It possesses an odour like that of oil of bitter almonds. [BENZOIC GROUP.]

HYDROBENZOINAMIDE. [BENZOINAMIDE.]

HYDROBROMIC ACID. [BROMINE.]

HYDROCARBONS. This name is applied to a very numerous class of chemical compounds consisting of carbon and hydrogen. The chief hydrocarbons whose constitution is well known are the monatomic and biatomic radicals, the double radicals, and the hydrides of the monatomic radicals. In addition to these, however, a host of other similar compounds of less certain constitution are met with amongst the products of the destructive distillation of animal and vegetable substances; the illuminating effect of coal gas, for instance, is due exclusively to certain gaseous and volatile hydrocarbons, whilst coal tar and wood tar are rich in the same class of compounds.

A large number of hydrocarbons, of which olefiant gas may be taken as a type, contain an equal number of equivalents of the two elements, their composition being expressed by the general formula CnHn, n representing an even number, as 2, 4, 6, &c. Two other families contain an excess of hydrogen; these are represented respectively by the formulæ CnHn + 1 and CnHn + 2. Another class, to which benzole belongs, has the composition CnHn—6, whilst naphthalin seems to represent a similar family of the form CnHn—12. Other hydrocarbons, of the form CnHn—1 and CnHn—7, appear also to exist, although they are less extensively known than the other families. As regards their state of aggregation, some hydrocarbons are gaseous, as olefiant gas, others liquid, as benzole, and others solid, as naphthalin and paraffin. The hydrocarbons of the form CnHn and CnHn—12 are readily acted upon by chlorine, bromine, and other agents; whilst the families CnHn + 1 and CnHn + 2 are remarkable for their great indifference towards chemical reagents, a characteristic which has given to one of them the name paraffin. [ORGANIC RADICALS; HYDRIDES.]

HYDROCELE (from ὕδωρ, water, and κήλη, a tumour) is a collection of watery fluid in the tunica vaginalis testis. It is characterised by the formation of a tumour, which enlarges gradually without heat or pain, has a pyriform shape, is firm and elastic, often appears transparent when a light is placed behind it, and does not, like a hernia, diminish in size when the body is in a recumbent posture, nor communicate any impulse when the patient coughs. In most cases the fluid collects without any distinct cause; but in some it follows rapidly after an injury of the part. The quantity of fluid which accumulates varies from a few ounces to four or six pints. The disease often occurs in those who are otherwise in perfect health, and in persons of all ages; it may be seated on one or both sides of the body. The treatment consists, 1st, in the evacuation of the fluid by tapping; and, 2nd, in preventing it from accumulating again by exciting such active inflammation of the opposite surfaces of the tunica vaginalis as may produce their adhesion and the obliteration of the cavity. The latter purpose is generally fulfilled by the injection of some stimulant fluid, or the introduction of a foreign body into the cavity.

HYDROCEPHALUS (from ὕδωρ, water, and κεφαλή, head), water in the head, is a name applied to two diseases nearly peculiar to infancy and childhood, which are distinguished as the acute and the chronic. These diseases differ entirely in their nature. Acute hydrocephalus is a disease rapid in its course and essentially inflammatory in its nature, and of which the effusion of fluid in the head is but one, and that not a constant effect or concomitant. To constitute chronic hydrocephalus (an affection which may last many years), the only essential condition is the accumulation of a watery fluid within the skull, which may or may not be caused by or attended with inflammatory action.

1. *Acute hydrocephalus* is a most frequent and fatal disease of the early stages of life. It occurs most commonly between the first and the eighth year, and corresponds in a great measure to the inflammation of the brain (phrenitis and arachnitis) of later years.

The rapidity of the disease when once formed, and its frequently fatal termination, render it a matter of the greatest importance to detect its first or premonitory symptoms. But these, which it frequently falls to the lot of the parents and friends only to observe, are unfortunately seldom so marked as to be thought to demand medical aid, and are indeed with great difficulty distinguished from the symptoms of other affections of far less formidable nature.

The child is perhaps liable to momentary giddiness while moving quickly, is fretful and nervous, and its rest is disturbed; it loses its appetite, its bowels are costive, and the motions offensive. The eyes become heavy and very sensible to light, the face is pale, and the features devoid of animation. There is more and more indisposition to motion; the little patient complains of heaviness of the head, and loses its strength; its gait is unsteady. Of the above symptoms, those referrible to the bowels are frequently most prominent: purgative medicine is given, and sometimes relieves the symptoms for a time. The child may remain in this state for several days or weeks without anything more than heaviness or slight pain in the head being complained of, and without any fever; but when the symptoms persist after purgative medicine has acted, they should be looked upon with apprehension; and if there be no known cause, such as the presence of worms in the intestines or the eruption of a tooth, to account for them, they should be closely attended to from the commencement.

The symptoms more surely indicative of the disease are more intense pain in the head, to which the child constantly carries its hand; intolerance of light, sound, and motion; squinting; heat of the head; knitting of the brows; disturbed sleep, with grinding of the teeth, the child frequently waking with a scream; the pulse being at the same time slow and irregular, and not quick as in fever from worms or teething. The appetite is lost, the evacuations from the bowels are unhealthy, and vomiting ensues. The abdomen, if previously distended, now falls in and becomes quite flat. Stupor, interrupted by screams, follows. After these symptoms have continued for some hours or days, there will sometimes be a temporary recovery of sense; the child will see, hear, and know its friends, and will take its food; but this promising state is soon interrupted by convulsions of the whole body, or of one side, paralysis of one side, return of the squinting, complete loss of sight and hearing, and inability to swallow; still greater emaciation ensues, the breathing becomes irregular, the extremities cold, and death follows.

This is the more usual course of the disease; it then generally lasts several days or even weeks. But it in some instances comes on suddenly, and proves fatal in a few hours. In other cases the symptoms are less severe and more prolonged; and chronic hydrocephalus gradually developes itself.

The appearances which are found in the brain after death are congestion of the blood-vessels, effusion of serum mixed with lymph in very variable quantity between the membranes at the base of the brain or in its cavities, and softening of the substance of the brain itself, particularly of those parts of it which form the floor of its cavities or ventricles. Sometimes there is merely effusion of clear serum, sometimes no effusion, but merely softening of the cerebral substance.

Causes.—Children of scrofulous diathesis, or of irritable temperament, and those of precocious intellect, with a large head, are most subject to this disease. It may in fact be essentially regarded as a disease of scrofulous origin. Scrofulous children should be as much as possible guarded from agencies likely to excite increased flow of blood to the brain, such as cold or external violence to the head, the influence of the sun, the suppression of eruptions of the skin, and particularly of the scalp, the use of narcotic remedies, as opium, too great excitement of the mind, and the early exercise of the intellectual powers.

The *treatment* must vary in the different stages of the disease, but will generally consist in endeavouring to subdue inflammatory action, in removing any causes which may, directly or indirectly by sympathy, keep up irritation of the brain; and lastly, in the latter stages, in supporting the strength of the system.

In order to subdue the disease in the inflammatory stage leeches should be applied to the temples, and some have even recommended the abstraction of blood from the jugular vein. Active purgatives should be administered, and the circulation should be controlled. Mercurials were formerly recommended, but the fact of the origin of this disease in a scrofulous habit has led to a considerable modification of this practice. When the active symptoms have been subdued, an alterative course, consisting of iodide of potassium with slight tonics, have been found most beneficial.

Spurious hydrocephalus.—There is a form of disease to which children are liable, and which has been called spurious hydrocephalus, which, with symptoms closely resembling the above disease, comes on, nevertheless, in an opposite state of the system. It arises from depletion, loss of blood, or active medicines. In these cases active remedies speedily destroy the life of the child. Dr. Watson states that as these cases are very difficult to distinguish from those of acute hydrocephalus, he is guided by the state of the unclosed fontanelle. If the unclosed fontanelle be convex and prominent, he regards it as indicative of the acute form of the disease; but if it be depressed and concave, he prescribes a better diet, ammonia, brandy, and arrow-root, instead of depletants.

2. *Chronic hydrocephalus.*—The disease to which this name is applied is correctly denominated water in the head, being always accompanied with a considerable collection of watery fluid in the cavity of the head, sometimes within the membranes of the brain only and exterior to the organ itself, but more frequently in the ventricles or cavities of the cerebral hemispheres, which are then distended to the form of a sac. The quantity of fluid is sometimes so great as to cause an increased size of the skull, amounting to great deformity; the face, remaining of its natural size, appears disproportionately small. The disease generally arises before or very soon after birth; and the cranial bones not being completely ossified at the time of its commencement, they become separated to a distance from each other, and the sutures remain open for a long period. When the disease comes on after birth its early progress is very insidious.

Symptoms.—The intellectual faculties are always deranged, and the senses generally more or less disordered; there is usually impaired vision or blindness, with squinting; speech is imperfect; the voluntary power over the limbs is partially lost, giving rise to an unsteady gait, as a frequent symptom. The digestive functions, respiration, and circulation, are in most cases unaffected until near the termination of the disease. The unfortunate patient is sometimes the subject of occasional epileptic fits. In the latter stages of the disease the loss of intellect and of the power of motion increases, till at last complete coma and paralysis ensue.

The duration of the disease is extremely various. It may terminate fatally even before birth, or the child may live for many months or years. A man named Cardinal, the subject of water in the head, died a few years since at Guy's Hospital, aged thirty-two years: and a woman is mentioned by Gall and Spurzheim as having lived to the age of fifty-four years, though after death four pints of fluid were found in her head.

The amount of fluid accumulated in the brain or its membranes is as various as the duration of the affection. It may not exceed half a pint or a pint, or it may reach the quantity of several pints. In the patient Cardinal, ten pints of fluid were contained in the head. Cases are recorded in which as many quarts have been found.

Causes.—The children of scrofulous parents, and those of a rickety diathesis, are most prone to chronic hydrocephalus. Any causes acting on the mother so as to interfere with the proper nutrition of the fœtus may produce it. Sometimes several children of the same parent are similarly affected from birth. Chronic hydrocephalus may be left as a consequence of the acute disease.

Treatment.—In the majority of cases medical treatment is quite useless, except in the early stage of the disease, and when it has come on subsequently to birth. If there are symptoms of subacute inflammation existing, the means calculated to subdue this are used with benefit. The next great object to be effected is to remove the accumulated fluid. This may be attempted by internal remedies supposed to accelerate absorption, or it may be effected by puncturing the head. The latter operation has been performed at different times by many surgeons, and in numerous instances with success.

HYDROCHLORIC ACID. [CHLORINE; *Hydrochloric acid.*]

HYDROCHRYSAMIDE. [CHRYSAMMIC ACID.]

HYDROCYANALDIN ($C_{18}H_{12}N_4$). A product of the action of hydrocyanic and hydrochloric acids upon aldehyde-ammonia. When these bodies are gently heated together they form alanin [ALANIN], but without heat the reaction produces hydrocyanaldin:

$$3\underbrace{\left.\begin{matrix} C_4H_3O_2 \\ NH_4 \end{matrix}\right\}}_{\text{Aldehyde ammonia.}} + \underbrace{3C_2NH}_{\text{Hydrocyanic acid.}} + 2HCl = \underbrace{C_{18}H_{12}N_4}_{\text{Hydrocyanaldin.}} + 2NH_4Cl + 6HO$$

Hydrocyanaldin is a neutral, insipid, and colourless crystalline substance. Heated with potash, it disengages ammonia, whilst the solution becomes brown from the separation of resin of aldehyde.

HYDROCYAN-HARMALINE ($C_{26}H_{14}N_2O_2, C_2NH$). An organic base composed of harmaline and hydrocyanic acid. It is best obtained by dissolving harmaline in a weak boiling solution of hydrocyanic acid, and then filtering whilst hot. As the liquor cools, the base crystallises out in thin rhomboidal tables, soluble in water and alcohol. It forms very instable salts with acids, which readily decompose into salts of harmaline and free hydrocyanic acid.

When nitroharmaline is treated in the same way, it yields another crystalline base, *hydrocyano-nitroharmaline*, having the formula $(C_{20}H_{15}(NO_4)N_2O_2, C_2NH)$. [HARMALINE.]

HYDROCYANIC ACID. [CYANOGEN.]

HYDROCYANO-NITROHARMALINE. [HYDROCYAN-HARMALINE.]

HYDRODYNAMICS. Under this word are usually comprehended the conditions of equilibrium and of motion in non-elastic fluids, with the resistances which they oppose to bodies moving in them. When a fluid is in a state of rest, the investigation of its equilibrium and that of bodies immersed in it, with the investigation of the pressure exerted by the fluid on bodies immersed in it, or containing it, form the subjects of hydrostatics. Hydrodynamics, which was formerly included under the term *hydraulics*, is concerned chiefly in investigating by mathematical reasoning, or in showing from observation and experiment, the laws relating to the discharge of fluids through orifices and tubes in vessels or reservoirs, and to their motions in canals or rivers.

Concerning the laws of the motions of fluids as they were known to the ancients, little can be said; the only notice of this branch of science, even in the time of the Roman empire, is contained in the treatise 'De Aquæductibus,' which was composed by Frontinus, in the reign of Nerva or Trajan. This writer shows that the quantity of water issuing from an orifice depends on its magnitude, and on the height of the water in the reservoir above the orifice; and he states that a short tube applied to an orifice permitted a greater discharge of fluid than could be obtained from a simple perforation of equal diameter. He appears, however, to be unacquainted with the manner of determining the velocity when the height or *head* of the water is given; and it is not certain that this elementary proposition was solved till the time of Torricellius, who, in 1643, assigned the law correctly, for that case only, however, in which the aperture is very small compared with the height of the water in the vessel or reservoir.

It appears that, even at the end of the 16th century, the cause of the ascent of water in pumps was little known; for Galileo, having occasion to make some observations on the phenomenon, could give no better reason for it than that it was caused by an attraction which he supposed the piston exercised on the water; and not being able to make the column of water follow the piston when the latter was about 34 feet above the surface of that in the well, he attempted to explain the circumstance by saying that the weight of the column was then so great as to overcome the attraction of the piston. We are indebted to Torricellius for the discovery that the rise of the water is owing to the pressure of the atmosphere on that which, in the well, surrounded the pump, and which is thus forced into the barrel, in consequence of the removal of the internal air, till the weight of the column raised is in equilibrio with that pressure. [BAROMETER.]

Castelli, a disciple of Galileo, in his treatise 'Della Mesura dell' Acque Correnti' (1628), appears to have been the first who applied himself to the investigation of the motion of fluids in rivers; and, together with several other circumstances relating to such motion, he shows that when the bed of a canal whose transverse section is variable has taken a permanent form, the velocities at different sections are inversely proportional to the areas of those sections. This branch of the science was subsequently much cultivated in Italy, probably on account of its connection with the important operations then in progress for improving the navigation of the Po and draining the marshes in the northern part of that country. The Marquis Poleni wrote, in 1695, a work entitled 'De Motu Aquæ mixto;' and, in 1718, another concerning the flow of water through orifices and short tubes; and numerous works containing the results of their investigations, and experiments relating to the same subjects, have been made public by other distinguished Italian mathematicians.

The 'Principia' of Newton contains (lib. ii., sect. 7) a series of propositions concerning the motions of fluids. In the first edition (1687) the law of the velocity of water flowing from vessels, being founded on experiments made with orifices of considerable magnitude, appeared to differ from that which had been observed by Torricellius; but the discovery of the *vena contracta*, which was introduced in the second edition (1713), explained the reason of the apparent discrepancy. Newton also investigated the resistance of fluids to bodies moving in them; and it may be said that his theory forms the groundwork of all our knowledge concerning that subject.

Daniel Bernoulli (in 1738) was the first who applied the higher branches of mathematical analysis in the investigation of general equations relating to the problems of hydrodynamics; and though objections were made to the principle which he adopted, yet the independent investigations of succeeding mathematicians have only confirmed the results at which the former had arrived. The subject was taken up in 1744 by D'Alembert, who, assuming that the motion of each horizontal lamina of fluid in a vessel, during its descent in consequence of the efflux from the orifice, is compounded of two motions, namely, that which it had at the moment preceding any given time, and that which is subsequently lost, arrived at equations containing, in the *implicit* form, all the circumstances attending the efflux at the orifice. And, subsequently, he investigated corresponding equations from the assumption, first, that a rectangular canal supposed to exist in a fluid mass which is in equilibrio is itself in equilibrio; and secondly, that a molecule of fluid supposed to be incompressible retains the same volume under a different form in passing from one place to another.

The researches of Euler, La Grange, La Place, and other Continental mathematicians have, since, contributed greatly to establish the principles of the science on an analytical basis. The laws of the motions of fluids in canals and rivers were, with every possible precaution to ensure accuracy, determined experimentally by the Abbé Bossut in 1771, and by the Chevalier Du Buat in 1786.

In investigating the circumstances attending the discharge of fluids through orifices it is usual, according to the theory of *Parallelism of Strata*, to suppose the fluid to be divided into an infinite number of indefinitely thin laminæ perpendicular to the axis A B (*fig.* 1) of the vessel in which it is contained, and that in the descent of the fluid these laminæ preserve their parallelism till they come near the orifice, when they assume the shape of a funnel, about which the fluid is stagnant. In the process immediately following, let the vessel be cylindrical or prismatical, in a vertical position, and have an orifice at B. Now if $pp'q'q$ be such a lamina, its distance from A being expressed by x, and its area (perpendicularly to the axis) by a, we shall have $a.dx$ for the volume of the lamina; also D being its density, we have $a\,\mathrm{D}\,dx$ for its mass. The force with which this lamina tends downwards is its gravity, and the resistance experienced in the descent is the excess of the pressure from below upwards over the downward pressure of that above the plate. If g represent the force of gravity, then $\mathrm{D}\,ag\,dx$ is equal to the action of gravity on the plate in its descent, that is, the *weight* of such a lamina.

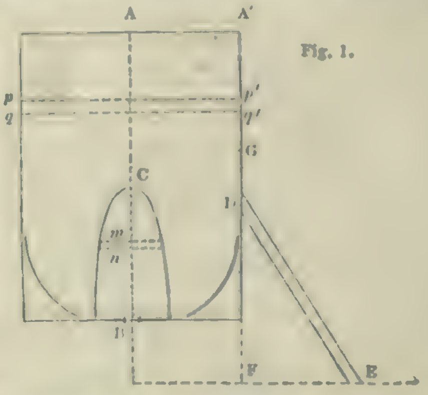


Fig. 1.

Let p represent the pressure exerted downwards by the water above, against any elementary portion of the lamina: then, the pressure of the water at the upper and under surfaces of the lamina being proportional to the depth of those surfaces below A, $p+dp$ acting upwards may represent that of the water below: hence the resistance of the water below the lamina will be $a\,dp$; and therefore the motive force by which the lamina descends will be $ga\,\mathrm{D}\,dx - a\,dp$. This being divided by the mass of the latter will (by mechanics) give $\frac{g\,a\,\mathrm{D}\,dx - a\,dp}{a\,\mathrm{D}\,dx}$ or $\frac{g\,\mathrm{D}\,dx - dp}{\mathrm{D}\,dx}$ for the accelerative force of descent. But in variable motions the accelerative force is expressed by $\frac{dv}{dt}$ (v being the velocity and t the time); or, since $v=\frac{dx}{dt}$, the accelerative force is expressed by $\frac{d^2x}{dt^2}$: therefore $\frac{d^2x}{dt^2} = \frac{g\,\mathrm{D}\,dx - dp}{\mathrm{D}\,dx}$.

But the quantity of water flowing through the orifice at B in any given time being evidently equal to that which would pass through the space $pp'q'q$, whose depth is dx, in the same time; if v be the velocity of a particle in its descent through the depth pq or dx, and u that of a particle in the orifice, we shall have, in the element dt of time (a' being the area of the orifice), $a'u\,dt = a\,dx$, or $dx = \frac{a'u\,dt}{a}$; whence, considering a, a' and dt as constant, we get $d^2x = \frac{a'\,du\,dt}{a}$: which, being substituted in the above equation for $\frac{d^2x}{dt^2}$, we obtain $\frac{g\,\mathrm{D}\,dx - dp}{\mathrm{D}\,dx}\,dt^2 = \frac{a'\,du\,dt}{a}$, or $ag\,\mathrm{D}\,dx - a\,dp = \mathrm{D}\,a'\,du\,\frac{dx}{dt}$.

But the equation $a'u\,dt = a\,dx$ gives $\frac{dx}{dt} = \frac{a'u}{a}$; therefore the last equation becomes $g\,\mathrm{D}\,dx - dp = \frac{\mathrm{D}\,a'^2u\,du}{a^2}$, whose integral is $g\,\mathrm{D}\,x - p = \frac{\mathrm{D}\,a'^2u^2}{2a^2}$ + constant; whence

$$p = g\,\mathrm{D}\,x - \tfrac{1}{2}\,\frac{a'^2}{a^2}\,u^2\,\mathrm{D} + \text{constant}.$$

Let $x = h$ (= A B) and $a = a'$, then

$$p = g\,\mathrm{D}\,h - \tfrac{1}{2}\,\mathrm{D}\,u^2 + \text{constant};$$

and subtracting this equation from the preceding, we have

$$o = g x - \tfrac{1}{2} \frac{a'^2}{a^2} u^2 - gh + \tfrac{1}{2} u^2.$$

This expresses, according to the theory of *fluid threads*, the relation between the velocity u and the difference between the weights of two filaments of the fluid having unity for the base of each, and whose heights are h and x. When $x = o$, the equation becomes $o = -\tfrac{1}{2} \frac{a'^2}{a^2} u^2 - gh + \tfrac{1}{2} u^2$; or considering the orifice as infinitely small so that a' and the whole first term of the second member vanishes, we have $o = -gh + \tfrac{1}{2} u^2$; whence $u = \sqrt{2gh}$.

Now gh expresses the weight of a prism of fluid having unity for the area of its base and whose height is h, h being the vertical distance of the surface of the fluid from the centre of gravity of the orifice, which is called the "*charge of water*" on the orifice; and this is the pressure of the fluid against a small orifice at the bottom of the vessel: but, while the height h is the same, the pressure is the same whatever be the position or inclination of the orifice: therefore $\sqrt{2gh}$ will express the velocity at the same depth, whether the orifice be at the bottom or side of the vessel. By the theory of dynamics this is equal to the velocity acquired by a body in descending by gravity through a height h, equal to that of the column of fluid, the orifice being infinitely small.

It may be concluded from the above theorem, that the velocity of a fluid spouting upwards through an orifice in a vessel would cause it to ascend to the level of the upper surface of that in the vessel, if the resistance of the air and of friction were abstracted. Hence we see that if Q = waste of water per second, m = a constant coefficient, d the surface of the orifice; then $Q = mud = md\sqrt{2gh}$. Now m is found to be always $= \cdot 62$ in orifices with thin walls; hence $Q = 4 \cdot 98 \sqrt{h}$. In orifices with a cylindrical spout, 3 or 4 times the size of the orifice, we shall have $u = \cdot 82 \sqrt{2gh}$, and the *waste* $= Q = \cdot 82 d \sqrt{2gh} = 6 \cdot 58 \sqrt{2h}$.

It follows, also, that the velocities of spouting fluids, at different depths below the upper surface, are proportional to the square roots of the depths; that the quantities of fluids discharged in equal times at different depths in the vessel, *the latter being constantly full*, are to one another in a ratio compounded of the areas of the orifices and the square roots of the depths; and the quantity of water which would be discharged in a given time t, through an orifice a in a vessel kept constantly full at the height h, is expressed by $a' t \sqrt{2gh}$.

The velocity u or $\sqrt{2gh}$ expresses the length of a cylinder of water which would flow through the orifice in one second; consequently the time of discharging, from a cylindrical or prismatical vessel, the area of whose base is a and whose height is h, a quantity of water equal to that which the vessel will contain, the latter being however kept full during all the time that the water is flowing, will be found by making ah equal to $a't\sqrt{2gh}$; whence t (the time required) $= \frac{a}{a'} \sqrt{\frac{h}{2g}}$. The value of g is 32·19 feet, or 386·28 inches; and in these values of u and t it is evident that the areas and height must be of the same denomination as g.

When a vessel is *suffered to discharge itself gradually*, the velocity of the effluent water diminishes continually. Now if x be the depth to which the water has descended at the end of the time t, h being the whole height when the vessel is full, $h - x$ will be the height of the fluid at that time; and we shall have $\sqrt{2g(h - x)}$ for the velocity in the orifice. This may be supposed constant during the time dt, and then the quantity of fluid discharged in that element of time would be equal to $a' dt \sqrt{2g(h - x)}$. In the time of this discharge the upper surface of the fluid will descend through the depth dx; therefore the area of the upper surface being a, we have $a\,dx = a'\,dt \sqrt{2g(h - x)}$, and $dt = \frac{a\,dx}{a'\sqrt{2g(h - x)}}$. If the vessel is an upright cylinder or prism, a is constant, and the integral of the expression is $t = -\frac{2a}{a'\sqrt{2g}} \sqrt{h - x}$ + constant. But, when $x = o$, we have $t = o$; therefore $o = -\frac{2a}{a'\sqrt{2g}} \sqrt{h}$ + constant; whence $t = \frac{2a}{a'\sqrt{2g}} (\sqrt{h} - \sqrt{h - x})$; which, when $x = h$, becomes $t = \frac{a}{a'} \sqrt{\frac{2h}{g}}$; and comparing this with the time in which an equal quantity would run off, *the vessel being kept full*, it will be found to be *double* the latter.

Next, if it were required to determine the quantity of water which would flow through an orifice of finite magnitude when cut in the vertical side of a vessel which is kept constantly full, it must be observed that the velocity of the effluent fluid at different points in the depth of the orifice varies as the square root of the distance of the point from the upper surface. Now let AB ($= h$) be the vertical height of the water in a vessel in one side of which is formed the orifice whose axis is CB, and imagine the horizontal ordinates at m and n to be drawn indefinitely near each other. Let $CB = h'$, $Cm = x$, the ordinate at $m = y$, $mn = dx$: then ydx is equal to the elementary area of the orifice; and the water flowing through the area in the time t, being that which is due to the height Am, is expressed by $t\,y\,dx \sqrt{2g(h' + x)}$; which, being integrated between $x = o$ and $x = h - h'$, would give the quantity of water discharged through the whole orifice in the time t. If the orifice were rectangular, y would be constant: suppose it $= b$; then the indefinite integral would be $b\,t\sqrt{2g} \int (h' + x)^{\frac{1}{2}}\,dx$, or $\frac{2}{3} b\,t \sqrt{2g}\,(h' + x)^{\frac{3}{2}}$, which (between the said limits) becomes $\frac{2}{3} b\,t \sqrt{2g}\,(h^{\frac{3}{2}} - h'^{\frac{3}{2}})$: and if the orifice extended from the bottom to the top of the vessel, having then $x = h$, or $h' = o$, the expression would be $\frac{2}{3} bt \sqrt{2g}.h^{\frac{3}{2}}$. If a rectangular orifice of the same form and magnitude were situated at the bottom B, with its longer side ($= h$) horizontal, the breadth b being very small in this, and also in the preceding case, the quantity discharged in the same time t, the velocity of the effluent water being now equal in every part of the orifice, and being that which is due to the whole height h, would be expressed by $b\,t \sqrt{2g}\,h^{\frac{3}{2}}$. The discharge found above is manifestly equal to two-thirds of this quantity.

In the second book of the 'Principia,' Newton shows that all the particles of water issuing from an orifice in a vessel do not pass perpendicularly to the side or bottom in which it is formed, many of them converging towards the orifice in every direction; so that after passing it they form a stream of diminished breadth, which he called the *vena contracta*. The section of the *vena contracta* may be taken as equal to 5-8ths of the actual orifice, as has been shown by Mr. Rennie, in his 'Report to the British Association,' for 1834.

M. Savârt has demonstrated the existence of certain *eddies* formed at the orifice by the issuing jet, caused by some water above the orifice trying to get out and coming into contact with the resisting walls, and by some water below it being moved by the falling mass above it, thus producing a set of forces acting by couples. Hence the issuing water, although it always has its motion of *translation* perpendicular to the resisting surface, has, besides, a *rotatory* motion caused by these eddies. The irregularities of this rotatory motion then tend to cause a disintegration of each successive section; and hence, between the thicker or *normal* drops there come out smaller ones, thus forming an irregular stream of varying width. Savârt has shown that each drop is formed by an annular enlargement at the orifice, which is propagated along the jet and causes this disintegration by a succession of such pulsations. The number of these is probably *directly* as the velocity of the jet, and *inversely* as the size of the orifice. It is remarkable that these pulsations are continuous enough to cause a clear musical note; and if with any instrument we produce the same note near, the pulsations become very regular, but cause no change in the amount or velocity of emission. When the orifices are not circular, curious variations in the geometrical figures, representing the sections at different distances from the orifice, are produced.

When, again, a rising column of water impinges against a horizontal plate, we have a remarkable appearance,—namely, a sort of disc of water, of which the interior is a transparent sheet, and the outer rim is a streaked space, along which lines of fluid stretch out and fall back in a very fine spray. The pulsations here, also, are very regular, and produce a musical sound. The relative size of the striated part to the whole varies with the position of the intercepting solid. When a certain distance is reached this part vanishes, and we have a wholly transparent sheet. The forms also vary very beautifully, according as the plate is perpendicular or oblique to the issuing jet. M. Savârt has also given some curious results on the subject of the clashing together of two liquid veins, which we have not room here to describe, but which will be found in the 'Annales de Chimie et de Physique,' vol. liv.; and a brief summary in Pouillet's 'Traité de Physique.'

We have been recently enlightened as to the phenomena of issuing jets by the researches of MM. Savary and Magnus. Bidone asserted that the *spiral* form of the jet was illusory; but Savary, when accounting for the curious dilations which he calls *ventral segments*, showed that the efflux itself gives a vibratory motion to the liquid vein, thus causing the protuberances in question. Prof. Magnus, in the 'Phil. Mag.' for February and March, 1856, regards every jet as composed of an indefinite number of united jets. He then examines the effect produced by the collision of two equal jets, coming centrally in opposite directions. These, as we should suppose from Savârt's experiments, spread out at the confluence into a flat plate perpendicular to the axes of the jets. When they meet obliquely, but centrally, they form a flat plate, not circular, but oval. This also we should imagine *à priori*; for the force of each jet may be resolved into two others, one parallel to the plane bisecting the angle between the jets, and the other perpendicular to it. The latter causes the elongation of the plate in a plane perpendicular to the direction of the force, as in the former case. When the water thus spreads out laterally, its motion does not cease, but the plate, by its cohesion, contracts in width, and collects into two new jets converging to one another. These then throw out a new plate perpendicular to the first, and the same process is repeated, forming thus a succession of elliptic plates in perpendicular planes, like the links of a chain.

Again, if two jets meet obliquely, but not centrally, the liquid plate is still formed, but it is no longer flat, being twisted by its cohesion with the unimpaired parts of the jets.

From these two last cases especially, Prof. Magnus has shown the formation of a single jet from an orifice to be due to the clashing of several jets at the *vena contracta*, thus throwing out between them a plate of an elliptic form, and so on throughout the whole liquid vein. The *chain movement* of the jet thus produced is easily converted into a *spiral* one by any slight impediment at the orifice, or by currents, even very slight, in the cistern, since all motion whatever of water in a cistern *necessarily* resolves itself into *rotatory* motion; because all other motions are destroyed by the sides of the vessel. Besides this, even when there is *perfect* stillness in the water of the cistern, rotation will take place at an orifice, by reason of the motion of the earth. This is well illustrated by Foucault's pendulum experiment. [GYROSCOPE.] It is evident from this, that everything on the earth's surface has *two* motions *relatively to the earth*—namely: one round the earth's axis in 24 hours; and another round an axis in itself, and parallel to the former, in the same period. The *latter*, in the case of a vessel of water, is resolved into two, one parallel to the liquid surface, the other perpendicular to it; neither being visible, because the vessel and everything else have the same motion. The horizontal rotation, in the latitude of Great Britain, will be about ⅕° per minute, so that the liquid has the rotation about its *vertical* axis. This will be abundantly sufficient to show the cause of the *spiral* motion of the issuing jet.

Prof. Magnus, by introducing a *tranquilliser*,—that is, a fan consisting of four radiating plates,—in order to destroy the effect of this rotatory motion on the jet, succeeded in showing that, in this case, *no* ventral segments or any other irregularities were produced,—perhaps not even the *vena contracta;* but the issuing column was perfectly smooth and uniform. M. Plateau, however ('Phil. Mag.,' Oct., 1856), denies this statement, and shows, by reference to his celebrated method of destroying the action of gravity on fluid veins, that a liquid cylinder is in stable equilibrium when its length and diameter do not exceed the limit of 3 and 3·6, being in unstable equilibrium beyond this limit, so that it is ruptured spontaneously into a series of isolated spheres with alternating spherules. This effect of the formation of various-sized spheres is well shown in the fusion of a platinum wire by a strong electric current. The wire is first elongated, and then, by the rupture of equilibrium of the parts, resolves itself, just as a liquid jet, into spheroidal particles.

Lastly, with regard to the formation of the *vena contracta* in such cases, we shall see that it must be formed, if we consider the theorem of Torricelli, as correctly representing the approximate velocity of any affluent jet. By this theorem, as before shown, we have the velocity at the orifice given by the equation $v^2 = 2gs$, where s is the distance from the surface to the orifice. Now, g is about 32·2 feet for the latitude of London: hence $v^2 = 64{\cdot}4 \times s$

$$\therefore v = 8{\cdot}025 \times \sqrt{s}.$$

But it is shown by experiment, that this *theoretic* velocity (given by substituting any value for s proper for the vessel in question) is 1¼ times the *actual* velocity, or this latter is ⅘ of the former; so that we must reckon the actual *height* of the surface, not from the orifice, but from the *vena contracta* itself, in which case Torricelli's theorem is in accordance with experiment.

The distances, measured on a plane passing through the base of a vessel, to which fluids will be projected from orifices at different depths in its side, may be easily determined (the resistance of the air being neglected) by combining the action of gravity on the particles of fluid after they have left the orifice with the velocity communicated to them in consequence of the pressure arising from the depth of the orifice below the top of the column; and the path of the filament may be shown, as in the theory of gunnery, to be a parabolic curve.

The results of experiments tend to show that, when the height of a head of water in a vessel and the diameter of an orifice in its base or side are given, the discharge of water through an *ajutage*, or tube inserted in the orifice (its length not exceeding three or four times its diameter), is to that through the simple orifice, nearly in the ratio of 12 to 11; and it is observed that, with a given diameter at its farthest extremity, the tube which is formed to coincide as nearly as possible with the natural figure of the vena contracta affords the greatest discharge. When the tube is fixed vertically in the base of a vessel, the effect is increased in proportion nearly to the length of the tube; since the velocity at the lower extremity of the tube is that which is due not merely to the height of the fluid above the base of the vessel, but to the height above the extremity of the tube. Again, if a short tube be applied horizontally to an orifice in the side of a vessel, the part nearest to the vessel having the form of the vena contracta, and, from the narrow part of the tube, diverging conically to the opposite end, the discharge of water is found to be more abundant than from a tube whose form beyond the vena contracta is cylindrical. For when the water has filled the tube, the cylindrical stream through the contracted part communicates its motion laterally to the rest of the water, till it causes the whole to acquire the same velocity. The quantity discharged in this case, compared with that discharged from a cylindrical tube, is considered to be nearly in the ratio that the diameter of the conical tube at its extremity bears to that of the vena contracta. The following is the result of some experiments on this subject, showing the use of an ajutage:—

A vessel with a simple hole . . .	discharged	62	quarts in 100 sec.
A vessel with a pipe whose length = 2 diameters of the hole . . .	"	82	" "
A vessel with the same pipe inserted only half way in the hole . .	"	63	" "
When the bottom of the vessel = the parabolic curve described by the particles	"	92	" "
With a bell-mouth added to this . .	"	a maximum.	

It is customary to express the slope, or inclination, of a pipe or canal, when uniform, by the quotient arising from the division of the vertical height of one end above the other by the whole length. But, in the case of a reservoir, as A B, having a conduit-pipe D E; let A A′ be the surface of the water, and E, in the horizontal line F E, be the lower orifice of the pipe. Then, if A′G express the height due to the observed velocity at E, G F will be the height necessary to overcome the friction in the pipe, and $\frac{\mathrm{G\,F}}{\mathrm{D\,E}}$ is considered as the effective slope.

The passage of water through long pipes is greatly retarded by adhesion and friction in the interior, by the resistance experienced where bends take place, and by the disengagement of air, which remaining stationary in the pipes when the latter are laid along a level surface, or rising to the higher parts of any vertical bends, opposes an obstacle and sometimes entirely arrests the motion of the water. Experiments alone can, at present, afford information concerning the amount of the retardation in pipes of given lengths and diameters; and those which were conducted by the Abbé Bossut at Meziéres in 1779 are the most complete of any which have yet been made. The water was allowed to flow through pipes whose diameters were 1⅓ inch and 2 inches, and whose lengths varied from 30 to 180 feet. They were chiefly of tin, and were inserted in the side of a reservoir in which the water during any experiment was always kept at one height; which was either 1 foot or 2 feet above the axis of the pipe. The general rules deduced from the experiments are,—that the discharges in given times, with pipes of the same length and with the same head of water, are proportional to the squares of the diameters; and, when the diameters are equal, the discharges are inversely proportional to the square roots of the lengths of the pipes. In order to afford the means of obtaining by calculation the supply which may be expected from a pipe of given dimensions, it may be assumed that when a pipe is 30 feet long and 1⅓ inch in diameter, the discharge at its extremity is about one-half of that which would be obtained from a simple orifice, or short tube, of the same diameter. The experiments made by M. Couplet at Versailles, in 1730, were with pipes whose lengths varied from 280 to 2340 fathoms, and the diameters from 4 to 12 inches. The pipes were of iron or stone, or of both combined, and they were bent in various directions both horizontally and vertically. A pipe whose length was 600 fathoms, and which was 12 inches in diameter, when the head of water was 12 feet, afforded a discharge amounting to about ⅒th; and a pipe of equal diameter, whose length was 2340 fathoms, when the head of water was 20 feet, discharged only ⅒th, of that which would have been obtained from a simple orifice. Bossut found that, in order to produce a continued discharge in a pipe, the head of water should be about 1⅓ inches in 180 feet.

The motion of water in the bed of a river depends on the action of gravity, by which the particles endeavour constantly to descend, and on the mobility of the particles, by which they are enabled to assume a level surface when at rest. The descent by gravity takes place in consequence of the difference, in a longitudinal section of the river, between the levels of any two points on its surface, whatever be the form of its bed; since the molecules of water, which are in every part of a transverse section, have equal facilities of moving in the direction in which, from the general slope, the motion can take place. And, by the nature of an inclined plane, the accelerative force by which a particle is moved is to that of gravity as the difference of level between any two points at the surface in a longitudinal section is to the distance between those points *on* the surface. That the motive force of the molecules composing a river depends on the upper surface only may be easily admitted, when it is considered that the bed may have any inclination and any degree of irregularity, yet if the upper surface be horizontal the water will be at rest.

If the water of a river experienced no resistance from the sides and bed, its motion would go on continually accelerating from its source to its mouth, like a solid body falling by the action of gravity; and the consequence would be, that besides the destruction ensuing from the violence of the torrents in the lower lands, the moisture would be drawn from the soils in the upper regions, which would thus become incapable of supporting vegetable and animal life. The adherence of the particles of water to each other, and the friction against the beds, produce together a resistance which increases with the velocity of the current, and becomes at length equal to the accelerative force of the descent; and then a uniform motion is established.

But when a current is in a state of equilibrium, the velocities in different transverse sections of the river may be very unequal, on account of the variations in the areas of those sections, through all of which the same quantity must flow in the same time; since otherwise the equilibrium of the river would not be permanent. It follows that the products of the areas of the sections multiplied by the velocities in each must be equal to each other, and that the velocities in different sections must be inversely proportional to the areas of those sections.

If the difference of level between any two points on the surface of a river or canal, in a longitudinal section, be equal to one inch, and if l, in inches, be the distance of those points on the surface, the slope of the river may be represented by $\frac{1}{l}$. Then, since the accelerative power of gravity vertically, is to the accelerative power on any plane, as the length of the plane is to its vertical height; we shall have $\frac{g}{l}$ for the accelerative power in a river whose slope is $\frac{1}{l}$. Again, if the resistances to the motion of the fluid were, as is sometimes the case, nearly proportional to the squares of the velocities, so that the resistance might be represented by $\frac{v^2}{m}$ (m being constant, and v representing the mean velocity); then (because when water in a river moves uniformly, the resistance is, as in all like cases, equal to the accelerative force) we should have $\frac{v^2}{m} = \frac{g}{l}$; whence $v = \sqrt{\frac{mg}{l}}$. But the resistances in canals and rivers are not strictly proportional to the squares of the velocities; and it is found by experiment that, in one and the same bed, $v \left\{ \sqrt{l} - \text{hyp. log.}\ \sqrt{l + 1{\cdot}6} \right\}$ may be considered as constant, and may be represented by $\sqrt{mg}$. Also, in beds whose transverse sections differ both in area and figure, when the mean radius is represented by r (where

$$r = \frac{\text{area ACB of the section}}{\text{arc ACB}} \Big) \textit{fig. } 2.$$

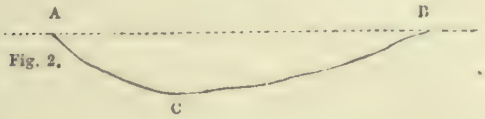

Fig. 2.

it is found by experiment that $\frac{\sqrt{mg}}{\sqrt{r} - 0{\cdot}1}$ is constant and equal to 307 inches; hence $\sqrt{mg} = 307\ (\sqrt{r} - 0{\cdot}1)$ and $m = 244\ (\sqrt{r} - 0{\cdot}1)^2$. Consequently we obtain

$$v \left\{ \sqrt{l} - \text{hyp. log.}\ \sqrt{l + 1{\cdot}6} \right\} = 307\ (\sqrt{r} - 0{\cdot}1),$$

or $v = \frac{307\ (\sqrt{r} - 0{\cdot}1)}{\sqrt{l} - \text{hyp. log.}\ \sqrt{l + 1{\cdot}6}}$. But further investigation leads to the conclusion that this expression for v must be diminished by $0{\cdot}3\ (\sqrt{r} - 0{\cdot}1)$ on account of the resistance by which the particles of water oppose a separation from each other. (Du Buat, 'Traité d'Hydrodynamique.')

As an approximation we may make $\sqrt{mg} = 307\ \sqrt{r}$, and $v = 307 \sqrt{\frac{r}{l}}$. And by experiment it has been found that if v' = the velocity at the surface of a river, v'' the velocity at the bottom, and v the mean velocity (all being expressed in inches per second), we shall have

$$v'' = (\sqrt{v'} - 1)^2 \text{ and } v = \tfrac{1}{2}\,(v' + v'').$$

The mean velocity in any one section may be practically found, tolerably near the truth, by placing in it a rod of wood loaded at one end with a weight sufficient to allow it to float upright in still water. The greater velocity at the upper surface will make the rod incline towards the direction of the stream; and, consequently, when it has acquired a state of equilibrium, it will float in an oblique position: the top of the rod will move slower than the water at the upper surface of the river, and the bottom will move faster than that in the lower part. Hence the mean velocity of the water in that part of the breadth of the river may be considered as equal to ·8 of the observed velocity of the rod. Often a Woltmann's drum is used, in which is a turning shaft, communicating by a screw-channel with a meter, and carrying four wings like a windmill. The experiment must be tried in different parts of the breadth of the river; and, in order to find the quantity of water which flows through the section in a given time, the area of the section must be obtained by measuring the breadth and sounding the depths at intervals across the river.

A knowledge of the velocity at the bottom of a river is of considerable use in enabling the hydraulic engineer to judge of the action of the stream on its bed; and it is evident that, to ensure permanency, the accelerative force of the water should be in equilibrio with the tenacity of the channel. The following table shows the superior limits

of the velocity which the water should have at the bottom of canals, according to their nature, without wearing them away:—

Weakened earth	2·5	inches per second.
Light soft clays	4·9	"
Sand	9·8	"
Gravel	19·7	"
Pebbles	19·9	"
Broken stones, flints	39·4	"
Agglomerated pebbles and schist	49	"
Rocks in layers	59·1	"
Hard rocks	98	"

Irregularities in the sides and beds of rivers, whether arising from natural causes, or produced by artificial obstructions, are the causes of currents setting obliquely across and of eddies being formed. These not only diminish the velocity of the water by creating impediments to its motion, but are sometimes seriously detrimental to the navigation, and to the stability of the structures which are founded in the bed of the river. When walls are made to project into the stream, the water striking them is forced to rise above its general level, on account of the obstruction; and is afterwards reflected towards the middle of the channel, with a velocity due to the rise thus produced. This current carries with it, by a lateral communication of motion, some of the water from the parts beyond the obstruction; the surface of the river being here, consequently, depressed, a portion of the water from the oblique current falls by gravity into the lower part, and thus a sort of whirlpool is formed at the place where the obstruction terminates. This process goes on continually; and the pressure upon the bed of the river under the whirlpool being diminished in consequence of the centrifugal force arising from the spiral motion, the water under the bed forces its way upwards, removing the gravel and sand, and frequently displacing the materials which form the foundation of the work there constructed.

When a body moves in a fluid at rest, its anterior surface being perpendicular to the direction of the motion; if an indefinitely thin lamina of fluid be supposed at every successive instant of time to be displaced, the resistance experienced by the moving surface may be considered equal to the weight of a column of the fluid whose base is the surface pressed, and whose height is that which is due to the velocity: that is to say, the resistance may be supposed to be equal to the pressure which would produce the same velocity at an orifice in the base or side of a vessel. A difference of opinion has however existed respecting the amount of the pressure sustained by the moving surface. For a vein of water issuing from a vessel and striking a plane surface at rest is shown by Newton ('Principia,' lib. ii., prop. 36), (and the fact seems to be confirmed by the experiments of Krafft and Bossut), to exert a pressure upon that surface equal to the weight of a column of water whose height is twice that which is due to the velocity. Du Buat, however, has proved that, even if such should be the case with respect to the central part of the impinging column of fluid, the mean pressure is less, on account of the lateral deviations of the exterior filaments, and the amount first stated above is that which is generally assumed.

If the velocity be represented by v, the height due to that velocity is equal to $\frac{v^2}{2g}$; then a representing the area of the moving surface, and D the specific gravity of the fluid, we shall have $\frac{a v^2}{2g}$ D for the pressure against, or the resistance experienced by that surface in moving through the fluid.

But when the anterior surface of the moving body is oblique to the direction of the motion, the resistance above found must be diminished on account of the inclination. Thus, let I be that inclination; the number of parallel filaments which act against a plane perpendicularly is, to the number which can act upon it in an oblique position, as radius (=1) is to sin. I. And by mechanics, the intensity of any force acting obliquely on any plane is a decomposed part of the whole force, and is to the latter in the ratio of sin.^{2} I to rad.^{2} (=1). Therefore the effective pressure against an oblique plane varies, as sin.^{2} I; consequently when the moving plane is oblique to the direction of its motion, the resistance which it experiences is to be expressed by $\frac{a v^2}{2g}$ D sin.^{2} I.

If a cylindrical body, terminated in front by an equilateral cone, move through a fluid in the direction of its axis; it can easily be shown that the resistance experienced is one-fourth, and if the body be terminated in front by a hemisphere, the resistance is one-half of that which would be experienced by the same cylinder if it were terminated in front by a plane perpendicular to its axis.

When a prismatical body is placed in a stream of water the effort necessary to keep it immovable in the fluid is equal to the difference between the pressures in front and behind. The pressure in front is equal to the sum of the pressure produced by the moving water and of the dead pressure, as it is called, which takes place when the body is at rest in still water; and the pressure on the rear face is merely equal to this last. When a body of that kind is made to move in a fluid at rest, its progress is retarded by the same difference of the pressures before and behind, and by the friction of the water against the sides. Additional causes of retardation are the heaping up of the water in front when the velocity is considerable, and a diminution of the pressure on the hinder face on account of the surface of the water there being depressed below the general level; a circumstance arising from the lateral communication of motion in fluids, by which the water, driven off from the front, and proceeding in a diverging direction on each side towards the rear, carries away with it from thence some of the water which should counteract in part the pressure on the front.

Mr. Scott Russell in the 'Report of the British Association,' for 1835, and Mr. Macneill in the 'Transactions of the Institution of Civil Engineers,' have given the following laws for the *resistance* to boats moving on canals; but for the practical reading of these laws we must refer to STEAM-BOAT.

1. The rise or emergence depends on the velocity of the vessel.
2. The resistance depends on the velocity or magnitude of the wave which is generated.
3. The resistance increases rapidly as the velocity of the body approaches the velocity of the wave, and is a *maximum* when they are equal.
4. If the velocity of the body be greater than the velocity of the wave, the resistance diminishes; for the body is poised on the summit of the wave in stable equilibrium.
5. The velocity of the wave is independent of the breadth of the fluid, but varies as the square-root of the depth.
6. In every navigable river there is a velocity with which it is easier to ascend against the current, than to descend with it.
7. Vessels on the summit of the wave *may* move about 20 or 30 miles per hour.

With regard to the form of vessel best adapted to diminish this resistance, they add:—

1. A cylinder will meet with *less* resistance in a fluid than a plate of the same dimensions as the end of the cylinder; and a cone with its *butt-end* foremost is better than either.
2. There is no fixed ratio of breadth to length which is best. The longer the better, but the breadth varies with the burden.
3. The section of greatest breadth should be always *abaft* the middle, about 3-5th of the length from the bow.
4. Lastly, the water-lines should be hollow, of the form called the "*wave-form*," first concave, then convex.

We may conclude this article with a notice of one of the many hydrodynamic engines, referring to separate heads, as indicated under HYDRAULICS, for other contrivances, in which the water is to be raised, or the force of water to be employed.

The HYDRAULIC RAM, which was invented by Montgolfier at the close of the last century, and improved by his son, consists, independently of the feeding cistern, of a pipe which carries the water to the head of operations. This part consists of a short tube, at the upper part of which, as well as at the end, are two valves, the *stop-valve*, and the *ascension-valve*; the extremity is in a bell filled in its upper part with air, and its lower with water. The ascension-valve being closed, the water will come from the reservoir with increasing velocity; and leaving it by the stop-valve, will shut it: then, by the *vis viva* which it has acquired, it will strike the ascension valve, and open it, and so penetrating into the reservoir of air, will compress it, and make the water in the ascension-tube rise; then the elasticity of the air, and the weight of water in the ascension-pipe will, of course, absorb partly the *vis viva* acquired with the water and will give it a powerful motion; hence, by reason of the retrograde motion of the water, the ascension-valve will shut, and there will be formed a partial vacuum under the stop-valve, which will open, and so on continually. Hence this machine, when once set in motion with a continual supply of water, will work by the momentum generated and destroyed for any length of time, if kept in repair.

The accompanying figure represents a vertical section of the improved construction. The water arrives from a cistern at a higher level, by the horizontal pipe A, over which is a circular opening containing a valve V, which acts as a *stoppage valve*, and is suspended by a stem. Further on the pipe ascends into a small reservoir C, called the *air matrass*; the air contained in it is compressed by the ascending water, while the lateral pressure of the water opens the valves V V′, and enters the larger reservoir F, which it partly fills, and compresses the air confined in the other part of it. The reaction of this air on the surface of the water causes the water to ascend the force-pipe G. When the stoppage valve is down, as in the figure, the water overflows the opening above it, and passes into a waste reservoir, thereby producing a rapid increase in the velocity of the current in A, which, acting on the under surface of the valve, forces it up, and closes the opening by which the water escapes. This momentary confinement of the water causes it to force its way into the cylinder C, where it compresses the air and produces a reaction, which opens the valves V V′, and a portion of the water enters the vessel F, and further compresses the air there. These resistances retard the current A, and relieve the stoppage valve from the impulse which raised it, so that that valve again falls, and the valves V V′ are closed. The water again escapes from the opening over the stoppage valve as shown in the figure, the current in A is again accelerated; the stoppage valve is once more closed, and the same series of effects is repeated. In this way by a series of pulsations water is continually elevated in the pipe G. As air is gradually absorbed by water, the compressed air of the vessels C and F is liable to be carried away by the water up the force-pipe G, the effect of which would be to subject the machine to shocks which would destroy the uniformity of its action and injure its working parts. To prevent this, an air-valve is provided at S, which, opening inwards, admits air during the intervals when the stoppage valve is closed. The air in rushing through the valve S makes the sound like the sniffling of a person's nose, and is hence called a snifting valve. It may consist of a tube of capillary bore, and be left entirely open.

HYDROGEN (H), an elementary body, which, as it is known only in the aëriform state, is usually termed hydrogen *gas*. From the earliest dawn of chemical science, elastic fluids have been known which had the property of burning on the approach of flame, and were confounded under the general name of *inflammable air*. As it was afterwards found that there was a difference in their densities, they were distinguished as *light* and *heavy* inflammable air; it is the former of these which is now called hydrogen. Hydrogen gas was first minutely examined, and the mode of preparing it in various ways stated, by Mr. Cavendish. [CAVENDISH, HENRY, in NAT. HIST. DIV.]

In nature, hydrogen is found in the free or uncombined state, as a constituent of volcanic gases. In comparatively small quantity it occurs associated with phosphorus, sulphur, carbon, and nitrogen, forming gaseous compounds; it is a constituent of nearly all the proximate principles contained in animals and vegetables; but united with oxygen, it constitutes $\frac{1}{9}$th of the total weight of that familiar compound—water.

Hydrogen is always prepared from water. If the gas is required absolutely pure, the water is decomposed by a current of electricity, the hydrogen being collected from the negative pole of the decomposing cell, and, if necessary, dried by being passed through a tube filled with pieces of chloride of calcium. Another process, valuable because instructive, consists in passing a fragment of potassium or sodium up into a small quantity of water in a test tube, the remaining portion of which is filled with mercury, and inverted over the mercury trough; the sodium rapidly attacks the water, combining with its oxygen to form oxide of sodium (soda), and displacing its hydrogen, which latter element, being gaseous, expels the greater part or all of the mercury from the tube. The following is the simple change that takes place:—

$$\underbrace{\mathrm{Na}}_{\text{Sodium.}} + \underbrace{\mathrm{HO}}_{\text{Water.}} = \underbrace{\mathrm{NaO}}_{\text{Soda.}} + \underbrace{\mathrm{H}}_{\text{Hydrogen.}}$$

For ordinary purposes, hydrogen is prepared by acting upon granulated zinc with diluted sulphuric acid. The zinc, covered with water, is placed in a bottle or other convenient vessel to which a cork can be fitted, and strong sulphuric acid is then poured in by means of a funnel, to which is attached a tube passing through the cork to the bottom of the bottle. The gas is rapidly disengaged, and passing through an exit-tube in the cork may be conveyed by flexible tubing into a gasholder, &c. [GASES, COLLECTION OF.] In this process, sulphate of zinc is formed, which remains in the generating vessel dissolved in the excess of water used.

$$\mathrm{Zn} + \mathrm{HO, SO_3} = \mathrm{ZnO, SO_3} + \mathrm{H}.$$

If it be required to produce hydrogen cheaply, though in a very impure state, it may be readily done by passing steam over iron borings heated to redness in a piece of iron gas-pipe. Under these circumstances the iron is converted into an oxide (Fe_3O_4), and the hydrogen set at liberty.

Hydrogen is an element. No amount of pressure causes it to abandon its gaseous condition. When pure, it is colourless, tasteless, transparent, and inodorous. It is the lightest body in nature, being sixteen times lighter than oxygen, and fourteen and a half times lighter than atmospheric air; its specific gravity is, therefore, 0·0692, air being taken as unity. One hundred cubic inches of it weigh only 2·14 grains.

This gas extinguishes flame; but when it meets with a supporter of combustion, as oxygen, it burns readily, with a continuous but feeble flame, generating much heat. When mixed with half its volume of oxygen, and the mixture is ignited by a taper, or by throwing into it a small quantity of platinum black, immediate and loud explosion ensues, attended with the formation of water by the combination of the gases; hence the name *hydrogen*, or the *water-producer*, from *ὕδωρ*, "water," and *γεννάω*, "I generate." It is irrespirable for any length of time, but when inspired for a short period it renders the voice remarkably but not permanently shrill; it does not appear to be poisonous, for when mixed with a due proportion of oxygen it may be respired without inconvenience; when it proves fatal, it seems to do so by the mere exclusion of oxygen.

It is very sparingly soluble in water, 100 cubic inches taking up only about one inch and a half of the gas; nor is there any other liquid which is capable of dissolving it in notable quantity. Hydrogen, neither in the gaseous state nor in solution, possesses either acid or alkaline properties. In its combinations it is powerfully electro-positive, and chemically plays more the part of a metal than of a metalloid.

In its separate state, hydrogen has not been applied to any very useful purpose; but on account of its extreme lightness it has been used to fill air-balloons; at present, however, coal-gas is substituted for aëronautic purposes, by reason of the facility with which it is obtained. This, however, from its greater density, requires much larger balloons than hydrogen gas.

When mixed with oxygen gas, and the mixture gradually burned in a small jet issuing from such a blowpipe as is described under Drummond Light, a temperature is produced sufficiently intense to melt platinum; and even if burned in the air, the oxygen of which serves as a supporter of combustion, a considerable degree of heat is generated.

When a very small jet of hydrogen gas is burned, the flickering nature of the flame causes musical sounds when a tube of glass or metal, or even of paper, is held over it. Such an arrangement is known as the hydrogen harmonicon, but any combustible gas will produce a similar effect.

The equivalent of hydrogen is 1, and its combining volume 2. Its combinations with other elements or radicals are called *hydrides* or *hydrurets*.

Hydrogen combines with oxygen in three different proportions, forming,—

1. Protoxide.	HO	water.
2. Binoxide	HO_2	oxygenated water.
3. Teroxide	HO_3	ozone.

1. *Protoxide of Hydrogen*, or *Water* (HO) will be treated of in a special article. [Water.]

2. *Binoxide of Hydrogen* (HO_2). To prepare this compound, twelve parts of binoxide of barium, obtained by passing oxygen gas over baryta heated to low redness, are dissolved in two hundred parts of water containing as much hydrochloric acid as will saturate about fifteen parts of baryta. Solution having been effected by gentle stirring, the whole of the baryta is then precipitated by a slight excess of sulphuric acid, added drop by drop. Another twelve parts of binoxide of barium are now added, and the precipitation of the baryta effected as before. This process is continued until about one hundred parts of binoxide of barium are consumed, care being taken to keep the mixture well cooled, and to filter it after every other addition of the binoxide. A tolerably strong solution of binoxide of hydrogen is thus obtained, containing, however, much hydrochloric acid. The latter is removed by the addition of sulphate of silver, and the sulphuric acid thus introduced got rid of by carbonate of baryta. Finally, the solution is placed in vacuo over sulphuric acid for a few days, when the water evaporates and leaves the binoxide of hydrogen. The latter body also volatilises in vacuo, but far less quickly than water.

Binoxide of hydrogen thus prepared must be kept in long glass tubes, closed with stoppers, and surrounded with ice. Notwithstanding these precautions, however, it slowly decomposes into water and free oxygen gas. It is a colourless, transparent liquid, of sp. gr. 1·452. It is unaltered by a temperature 54 degrees below the freezing point of water. It has a harsh, bitter taste, bleaches litmus paper without reddening it, and when placed on the hand whitens the cuticle and produces violent itching. Heat rapidly decomposes it. Contact with most metallic oxides not only causes violent separation of oxygen, but at the same time the oxides themselves are reduced to the metallic state. Binoxide of hydrogen appears to combine with some of the hydrated acids, as it is far less decomposable in their presence than when alone.

Oxygenated water is a term that has been applied to binoxide of hydrogen, but is now usually restricted to the solution formed by saturating water with oxygen gas.

3. *Teroxide of Hydrogen* (HO_3). The gases that are evolved when water is decomposed by a current of electricity are well known to possess a peculiar odour. The body that communicates this property has for some years been called *ozone* (from ὄζω, "I smell"); but it is only recently that M. Baumert has proved it to be the teroxide of hydrogen. The presence of hydrogen in this remarkable compound M. Baumert demonstrated by passing the gases (oxygen and ozone) evolved from the positive pole of a water-decomposing apparatus through a long drying tube containing pumice-stone moistened with sulphuric acid, and then through a tube the inner surface of which was coated with anhydrous phosphoric acid, and one portion of which was gently heated; water was thus produced, and made evident by the solution of the film of phosphoric acid on that part of the tube through which the gas was making its exit, while the film on the opposite part was quite unaltered.

Teroxide of hydrogen decomposes iodide of potassium, the excess of oxygen it contains—over and above that necessary to form water with its hydrogen—liberating its equivalent of iodine from the iodide of potassium, just as chlorine or bromine does. Taking advantage of this fact, M. Baumert ascertained the composition of ozone, prepared as above, by passing the gas for several hours through a weighed bulb apparatus containing iodide of potassium solution, with an arrangement for preventing loss of water by evaporation. The increase in weight after that time gave the quantity of ozone that had passed into the apparatus; an estimation of the iodate of potash formed, showed how much oxygen, exclusive of the elements of water, was contained in that weight of ozone, while the difference between the weight of the oxygen and the total increase in weight of the apparatus, gave the weight of water that had been formed from the decomposition of the ozone. The mean of three such experiments proved that the ozone in question was teroxide of hydrogen, thus:—

	By calculation.	By experiment.
H . . .	4	4·1
3O . . .	96	95·9
HO_3	100	100·0

Other Compounds of Hydrogen.—With sulphur, selenium, iodine, bromine, chlorine, fluorine, and tellurium, hydrogen forms combinations called *hydracids*. With nitrogen, it forms the powerful salifiable base ammonia; and with phosphorus, arsenic, antimony, and potassium, it forms the several hydrides. A description of each of these compounds will be found under the name of the element with which the hydrogen is united.

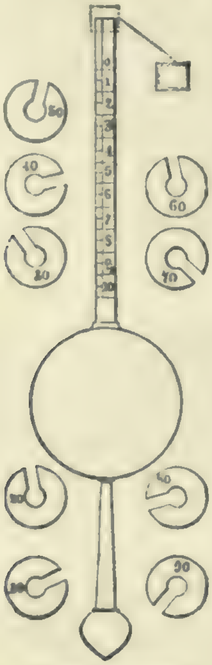
HYDRO'METER (ὕδωρ, water, and μέτρον, a measure) is an instrument for determining the relative densities or specific gravities of fluids. The principle of the hydrometer is this: It is known that when a body is immersed in a fluid, it loses as much of its weight as is equal to the weight of that portion of the fluid which it displaces. [Hydrostatics.] Thus, if a body suspended from the extremity of one arm of a balance be counterpoised by weights applied to the other arm, and while thus suspended it be immersed in a vessel of water, it will be found that one arm of the balance will preponderate, and that, in order to restore the equilibrium, as much weight must be applied to that arm from which the body is suspended as is equal to the weight of the water displaced. Hence, if the same body be immersed successively in two different fluids, the portions of weight which it will thereby lose will be directly proportional to the specific gravities of those fluids; because the diminution of weight is always equal to the weight of the fluid displaced,—that is, to the magnitude of the body multiplied into the specific gravity of the fluid. The above supposes the body to be specifically heavier than the fluid. If it be lighter, it will float upon the surface, so that its tendency to descend, or its weight, will then be entirely counteracted by the fluid; from which it appears that, when a body floats upon the surface of a fluid, the weight of the portion of fluid displaced is equal to the entire weight of the body. Now, since the weight of the fluid displaced by a floating body is constant (being always equal to the weight of the body), whatever may be the density of that fluid, it is obvious that if we can determine how much of the body is immersed, we may immediately deduce the specific gravity of the fluid; because, when the weight is constant, the specific gravity varies inversely as the bulk.

Upon this principle is constructed the instrument known by the name of *Sykes's hydrometer*, which is that employed in the collection of the spirit revenue of Great Britain. It consists of a thin brass stem about six inches in length, passing through and soldered to a hollow ball of the same material, and about one inch and a half in diameter.

To the inferior extremity of the stem, from which the hollow ball is about one inch distant, a permanent pear-shaped weight is attached; so that when the instrument is placed on a fluid, the other extremity may float perpendicularly to the surface. There are also ten weights of different magnitudes, nine of which are circular, and applicable by means of a slit to the lower branch of the stem. These are marked 10, 20, 30, 40, 50, 60, 70, 80, and 90 respectively, and by their successive application the instrument may be sunk so as to obtain the complete range of specific gravity, from that of pure alcohol to that of distilled water. The other weight is of the form of a parallelopiped, and may be fixed when necessary to the upper branch of the stem. The upper branch of the stem is divided into ten equal parts or degrees, each of which is subdivided into two parts. The whole is adjusted at the temperature of 60° Fahr., and tables are computed whereby the necessary corrections may be determined for all variations above or below that point. In order to determine the strength of spirit by means of the hydrometer, a portion is placed in a tall glass cylinder, and the temperature observed. One or more of the circular weights is then attached to the lower stem of the instrument, so that the lower extremity of the scale may sink beneath the surface of the fluid, and when the whole has become stationary the number upon the scale in contact with the surface of the fluid is observed. This number added to the number marked upon the circular weight employed will give a third number, adjacent to which, in the tables above mentioned, and under the head of the proper temperature, will be found the per centage of strength required.



Sykes's Hydrometer.

The most convenient method of obtaining the specific gravities of fluids is by means of what chemists call a *specific gravity bottle*, or *a thousand grain bottle*. This is a bottle of a globular form, with a ground-glass stopper, so adjusted as to contain exactly 1000 grains of distilled water, at the temperature of 60° Fahr., and accompanied by a weight, which is an exact counterpoise for the bottle when thus filled. In order to determine the specific gravity of a fluid by this means, it is simply necessary to fill the bottle with that fluid at the temperature of 60°, and place it in one of the scale-pans of a delicate balance, the counterpoise being placed in the other scale-pan; then the number of grains which it will be found necessary to add to one of the scale-pans, in order to produce equilibrium, will be the difference between the specific gravity of the fluid and that of water taken at 1000. For example, the bottle filled with the sulphuric acid of commerce will require about 845 grains to be added to the counterpoise to produce equilibrium, whence we say that the specific gravity of such a sample of sulphuric acid is 1·845. Whereas if the bottle were filled with spirit of wine, we should have to add weights to the scale-pan containing the bottle, and in the case of what is called *proof spirit*, 80 grains would have to be so added, in which case the specific gravity would be 0·920. [Alcoholometry; Specific Gravity.]

Various forms of hydrometer have been contrived under different names, one or two of which we may mention, such as the *Aræometer* (from *ἀραιός*, "light" or "thin," and *μέτρον*, "a measure"). This is employed for the purpose of ascertaining the specific gravities of fluids, generally such as are less dense than water, but it may be used to determine those of any fluids, and also of solid bodies. Its best form is probably that which was devised by Nicholson. The instrument which bears the name of that experimenter consists of a hollow cylinder, or sphere, of copper, from each extremity of which proceeds a stem; that which, when the instrument is in a vertical position, is uppermost, is a wire of hardened steel about 1-40th of an inch in diameter, carrying at its top a small cup, in which weights may be placed: to the lower stem, which is short, is attached a stirrup carrying a cup in which may be placed a solid body whose specific gravity it may be required to determine. The instrument is so adjusted, that if a weight equal to 1000 grains be placed in the upper vessel, the whole will sink in distilled water at the temperature of 60° Fahr., till a mark made on the stem is on a level with the fluid surface. When the specific gravity of a fluid, whether lighter or heavier than water, is to be determined, the instrument is plunged into the fluid, and weights are placed in the upper vessel till the mark on the stem is at the surface; then, if w in grains be the weight of the instrument when unloaded, and w' the weight placed in the vessel as just said: also if s be the specific gravity of distilled water, and s' that of the fluid in which the instrument is placed, we have, by hydrostatics,

$$w + 1000 : w + w' :: s : s';$$

whence s' may be found.

To obtain the specific gravity of a solid which does not imbibe water: after placing the instrument in distilled water, let the body be laid in the upper vessel, and weights, in grains, added till the mark on the stem is at the level of the surface; these weights being subtracted from 1000 grains, leave the weight of the body in air; then placing the body in the lower vessel, let other weights be added in the upper one till the mark on the stem is again at the surface of the water; these additional weights will express the loss which the body sustains by being immersed in water. Consequently if w'' be the weight of the body in air, w''' the loss just mentioned, s the specific gravity of the water, and s'' that of the body, we have by hydrostatics,

$$w''' : w'' :: s : s'';$$

whence s'' may be found.

If the substance whose specific gravity is required be, like wood, capable of imbibing water during the experiment, it should be left in the lower vessel, while under water, till the instrument is stationary, when the additional weights in the upper vessel will express the weight of the displaced water, together with that which is imbibed; then, having dried the surface, let the substance be placed in the upper vessel and weighed in air as at first: the difference between this weight and that which was found before the substance was put in the water, is the weight of the water imbibed; and this must of course be subtracted from the observed weight of the substance in water, previously to substituting the values of the terms in the last proportion.

For fluids of greater specific gravity than water, such as the concentrated acids, an instrument of the like kind which was invented by Guyton de Morveau, and is designated "gravimeter," may be used. (Gregory's 'Mechanics,' vol. ii.) Instruments of this kind, however, are seldom resorted to, the best plan being to make use of the hydrostatic balance, as will be more particularly described under Specific Gravity.

HYDRONITROFERROCYANIC ACID. [Cyanogen.]

HYDRONITROPRUSSIC ACID. [Cyanogen.]

HYDROPERSULPHOCYANIC ACID. [Cyanogen.]

HYDROPHO'BIA (from ὕδωρ, water, and φόβος, fear) is the disease occasioned by inoculation with the saliva of a rabid animal, and is so called from the violent and suffocating spasms of the throat which occur when the patient attempts to drink, or when, in the latter stages, the mere idea of drinking arises in his mind. The disease is never produced in man by any other cause than the saliva of a rabid animal: those cases which have been said to arise spontaneously have not presented all the true characters of the affection, and have in general been only severe cases of hysterical or other convulsions, in many of which the imagination and the fear of real hydrophobia had much influence. Whether it is ever spontaneously generated in animals is less certain, because its origin in them is less easily traceable; but the fact that it is possible to ward off the disease from packs of dogs, in which every fresh comer is submitted to a kind of quarantine, and the many instances now known of isolated situations in which, although dogs are very numerous, no case of hydrophobia has occurred for many years, tend to prove that in the dog also it arises only in consequence of the bite of some other rabid animal. It is probable that all animals are subject to hydrophobia, for all that we have an opportunity of observing, that is, all our domestic species, are; but it has not appeared that any, except the wolf, fox, cat, and dog, are capable of communicating it to each other, or to other species. There is no evidence whatever to prove that the disease can be communicated from one human being to another; men affected by it are not disposed to bite, and it is doubtful whether, if they did bite, the saliva would have any effect, for the experiments made with it upon animals are as yet contradictory and inconclusive.

The disease may be communicated to man either by the saliva being carried into a wound made by the tooth of a rabid animal, or by its being placed on the surface of a previous wound, as where dogs have licked the hand or face of a person on which there was any raw surface. However, it is only a small portion of the bites which a mad animal gives that convey the disease; if, for example, he bites through the clothes, there is a great probability that all the saliva will be wiped off from his teeth as they pass; and hence wounds of the hands and face are generally the most dangerous. It is probable, too, that the saliva differs in the degree of its virulence in different animals; the bite of the mad wolf seems generally more fatal than that of the dog. In a case known to John Hunter, twenty-one persons were bitten by the same dog, and only one had hydrophobia; in another, a wolf bit seventeen persons at Brive, and of these ten died by hydrophobia; in a third, fifteen persons were bitten by a dog, in ten of whom the wound was on the flesh, and three died. In none of these cases had any preventive measures been used; and from the evidence collected from various sources, Dr. Hamilton ('Remarks on Hydrophobia,' vol. i.) thought that whether preventive means were employed or not, only one person in twenty-five of those bitten by mad dogs would have hydrophobia. It appears that animals are more subject to the disease than man; for in a case where a dog bit four persons and twelve dogs, all the dogs died, but not one of the men. These results, although they should not prevent the surgeon from employing those measures which prevent the disease, fully explain how empirical remedies have obtained so much credit, the immunity from the disease being attributed to their influence, when it would have been as complete if they had never been used.

The period after the inoculation at which the symptoms of hydrophobia may exhibit themselves varies greatly. In the ten persons already mentioned who were bitten by the wolf, one was affected on the sixteenth and another on the sixty-eighth day after their wounds were received; in the five bitten by the same dog, the deaths occurred between the thirtieth and sixty-third days. In general the disease appears between the thirtieth and fortieth days from the injury; but cases are known where it has been delayed as long as eighteen months, and Dr. Bardsley believes that a person who has been bitten and used no preventive measures cannot be considered as perfectly safe till at least two years have elapsed. Cases are indeed recorded in which there was no evidence of injury for ten and twelve years before the disease manifested itself, but at present neither the number nor the accuracy of such histories is sufficient to allow any safe conclusion to be drawn from them.

The bite of a rabid animal generally heals up like that of a healthy one; there is nothing whatever which would indicate danger from it, and the patient is attacked when he has forgotten that he was ever bitten. In some cases, however, before hydrophobic symptoms appear, the scar of the wound becomes painful, red, and swollen, and pain is felt shooting from it along the course of the nerves of the part, as if it were going to ulcerate. The first decided indication of the disease is that the patient has headache and general uneasiness; he loses his appetite, and when he is about to drink he suddenly feels an aversion to any liquid, and is choked by any attempt to swallow it. He generally discovers this inability to drink accidentally, and often expresses his wonder that he should not be able to quench his thirst. The symptoms, once set in, rapidly increase in severity; any attempt to drink, and even anything that can suggest the idea of drinking, as the sound of liquid poured from one vessel into another, or the bright shining surface of polished metal looking like the surface of water, is sufficient to bring on the most frightful spasms of the throat, threatening instant suffocation, and producing the most severe pain. The convulsions, which were at first limited to the muscles of the throat and of deglutition, after a short time extend to other parts of the body; there is a constant agitation of the limbs, and a remarkable degree of nervous excitement; the patient is restless, anxious, and timid; his eye has a peculiarly unsteady glistening appearance, and he is often delirious, and talks with the greatest rapidity and earnestness to persons who are not present, or he thinks that his attendants are going to rob or murder him, and is haunted with frightful visions. As the disease proceeds, the convulsions of the throat become more frequent and severe; a breath of cool air, or the slightest noise or vibration of the room, is sufficient to excite them: there are severe headache, a rapid pulse, a foul tongue, and other symptoms of a generally disordered condition of the system. A copious secretion of thick tenacious mucus clogs up the air passages, and increases the feeling of suffocation, and it is in his attempts to free himself from this that the patient coughs and makes a loud harsh noise, which has been supposed to resemble the barking of the animal by which he was bitten. Sometimes there is furious delirium; but often for the last few hours of life the patient becomes quiet: he falls perhaps into a tranquil sleep, as if fatigued by his exertions, or he lies perfectly still, without spasms, and rational; but it is only a deceptive calm which presages his death; he rouses from his tranquillity, and, after one or two comparatively slight convulsions of the throat or of the whole body, expires. The duration of the disease is very rarely more than six days, and it often terminates fatally in twenty-four hours. In the latter cases the patient usually dies suffocated by one of the spasms of the throat; in the former he may have several remissions, in which the severity of the affection greatly decreases, and which may for a time seem to afford a hope of recovery. In most cases solids can be swallowed without much difficulty; and it is remarkable that in those who have been bitten by mad cats there is far less aversion to water than in those who have received the disease from the other species.

Nothing can at present be regarded as certainly known of the true nature of hydrophobia. Dissections of those who have died of it have shown the effects, but not the causes of its symptoms; as redness and turgescence about the throat and larynx, and general congestion from the frequent suffocative attacks. With this ignorance of its nature there is unfortunately an equal ignorance of any mode in which it may be treated with a prospect of success; for of all the medicines recommended (and probably no disease has been more variously treated) there is not one which has sufficient evidence to prove that it has been of the least avail, except in temporarily mitigating the symptoms. Opium in very large doses will produce quietude and great comfort to the patient by warding off the attacks of spasm, and will prolong, though it will not save life; and large bleedings have been useful in lessening the severity of the convulsions, and large doses of hydrocyanic acid have controlled the symptoms for days. But the only question that can be satisfactorily considered is that of prevention, which is accomplished by the removal of the morbid saliva from the wound before it has had time to produce its fatal influence on the body. Excision is at once the safest and most simple means, and whenever it is practicable should be employed as early as possible; the parts bitten should be completely cut out, with some of the sound tissues around them, and care should be taken that the very bottom of the wound is removed; for if a portion of the wounded surface remain, the patient is not secure. In some cases, however, as where the wound is superficial but extensive, or where it is situated on the face, or near an important organ, excision may be deemed unadvisable, and in these the best remedy is some violent caustic: pure nitric acid, or fused potash, or nitrate of silver, should be applied freely over the whole surface of the wound, so as to decompose every particle of the saliva. A third means is the careful washing of the wounds, but it is one on which it would be imprudent entirely to rely, though it should always be diligently employed until medical assistance can be obtained, and is useful after the parts have been cut out. The best mode of washing the wound is to pour water at a temperature of 90° or 100° on it, from a height of four or five feet, through the spout of a tea-kettle, and it should be continued for two or three hours, unless the other means are resorted to. It is not yet known at how late a period after the infliction of the injury it would be useful to remove the parts bitten; but considering the length of time during which the poison remains latent, and the probability that during that time it has only a local influence, it would certainly be prudent to remove the wounded parts after a lapse of even many days. Of course the value of these means is open to the objection already mentioned, that even when the patient does not suffer from hydrophobia it is uncertain whether his immunity depends on the measures employed; but it may be sufficient to state, that while every other remedy has frequently been unavailing, excision, when carefully employed, has been invariably successful, and the caustic has very rarely failed.

As a large majority of the cases of hydrophobia which occur in this country are the consequence of the bite of the mad dog, it may be useful to add the symptoms which he presents when in that state. He grows sullen and snarly; he leaves his home and runs about wildly, biting at whatever approaches him, though he will seldom go out of his way to attack, and he constantly gnaws grass and straws and pieces of wood or stone. To those, however, with whom he associates his demeanour is at first unaltered, and he caresses them as usual; and hence the cases in which death has followed the licking of a wound by dogs who showed no symptom of hydrophobia. It is an error to imagine that the mad dog avoids the water, for he will both drink it and swim in it as usual, and without presenting any of that horror of it which characterises the disease in man. Towards the close of the disease he grows more furious, gnawing and biting at everything around him, and frothing at the mouth. The disease is as incurable in the dog as in man, and usually lasts about the same length of time.

HYDROPS PERICARDII, or HYDROPERICARDIUM (from *ὕδωρ*, water, and *περικάρδιον*, the pericardium), is a collection of an unnatural quantity of fluid in the sac containing the heart. [Heart, Diseases of.]

HYDRORHODEORETIN. [Convolvulic Acid.]

HYDROSTATIC BALANCE. [Specific Gravity.]

HYDROSTATIC BELLOWS. [Hydrodynamics.]

HYDROSTATICS is the science which relates to the pressure and equilibrium of the fluids commonly called non-elastic, or incompressible, as water, mercury, &c., and to the equilibrium of bodies immersed in them. The elastic fluids, as air, steam, &c., are the subjects of pneumatics.

The two books of Archimedes, entitled, in Latin, 'De Humido Insidentibus,' contain all that is known concerning hydrostatics, properly so called, among the ancients. That philosopher showed from experiment that a mass of fluid will be in equilibrio when each of its particles is pressed equally in every direction. He explained that a floating body is held in equilibrio when its centre of gravity and that of the displaced fluid are in one vertical line; and that when bodies are immersed in a fluid of less specific gravity than themselves, they lose certain portions of their weights. The latter principle led him to the means of ascertaining the quantities of two different ingredients when mixed together in one mass; and he applied it in detecting the quantity of alloy in a golden crown which had been executed for the king of Syracuse.

The science of hydrostatics must, of course, be subject to all the laws of equilibrium of ordinary statics. [STATICS.] But there are two fundamental axioms which make it a distinct branch of that science, namely, (1), that *all* action between two fluid surfaces, or between a fluid and a solid surface, is *normal* to the plane in which they meet, that is, there is no such thing as *statical fluid friction*. This is the case, as far as we know, with all *perfect*, or non-viscous fluids. (2), That the amount of pressure at any point is independent of the *direction* of the surface pressed.

The cause of fluidity in bodies has been the subject of much discussion: it has been supposed to depend on the globular form of the particles, or on the caloric contained between them; or, finally, on both these circumstances combined. But, whatever be the primary cause, it is admitted by all that the property must arise, immediately, from the perfect mobility of the particles among one another; in consequence of which the mass immediately takes the figure of any vessel in which it is received, its upper surface assumes a level position, and by which, also, it begins to flow as soon as an orifice is made in any part of the sides or bottom of the vessel. Some difference exists however in the fluidity of different bodies: such as mercury, water, &c., which in their ordinary state possess this property in a high degree; while the particles of many fluids, as the oils, have a sensible adhesion to one another. With the exception of pure alcohol, all the non-elastic fluids, at certain temperatures, become congealed, and thus entirely lose their fluidity.

Since pores are known to exist between the particles of all bodies, fluid as well as solid, it may readily be conceived that no fluids can be absolutely incompressible: and experiments have been made from which it is manifest that spirit of wine, oil, water, and even mercury, can, by pressure, be reduced in volume, in certain degrees; the fluids which have the greatest specific gravity suffering the least compression. But as this diminution is very small when compared with the volume of the fluid (being for water, according to the experiments of Œrsted ('Trans. of Royal Society of Sciences at Copenhagen,' 1818 1822), only $46\frac{3}{10}$ millionths of its bulk for the pressure of one atmosphere, or about 15 lbs. on the square inch) for all practical purposes of hydrostatics such fluids may safely be considered as experiencing no change of volume by the compressions to which they may become subject.

Experiment has also shown that all the non-elastic fluids possess the property of transmitting equally in every direction the pressure exerted against any point on their surface. If, for example, a piston were forced into an orifice made in any part of the side of a vessel containing such a fluid, the effect of the pressure would be experienced equally at every point on the whole surface of the vessel. This property has hence been denominated the *quàquâversus* propagation of pressure; and it may be conceived to result from that perfect mobility of the particles among one another which has been above alluded to, and which enters into our first conception of fluidity.

But the pressure exerted by a fluid against the sides and base of a vessel in which it is contained, in consequence of a force thus partially applied, should be carefully distinguished from that which is caused by the gravity of the fluid: the former being the same in every part of the fluid mass, while the latter, at every point in the sides, depends on the depth of the point below the upper surface of the fluid.

It has been said above that a fluid in any vessel will have its upper surface in a level plane, or in a horizontal position; but it must be observed that, since the fluids on the earth are attracted towards the centre of gravity of the earth (leaving out the consideration of all disturbing forces, and considering the earth as a sphere), the particles must dispose themselves every way spherically about that centre; and consequently the upper part of a fluid in any vessel must be understood to form a portion of a spherical superficies concentric with that of the earth.

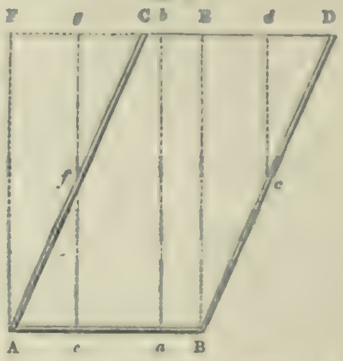
When, however, a mountain is near a sea, the level of the sea must be deflected somewhat upwards towards the mountain. If the Cordilleras, for example, were a hundred times higher than they are, the sea would slope upwards along the shores of America on both sides, and the ports of France and England, with those of Japan and China, would be left drained.

The quàquâversus pressure above mentioned has long since been proposed to be employed as a means of transmitting the action of a moving power to any distance, however great. For this purpose it has been projected to fill with water a horizontal tube having at each extremity a short arm in a vertical position; and in each of these arms to have a piston. Then that which is at one end of the tube having received the action of the moving power, it will, by means of the fluid, transmit the motion to the other; the rod of which should be in connection with the machinery on which it is intended to act.

From the same property it follows that if a fluid at rest in a vessel be supposed to consist of an infinite number of filaments, or infinitely slender columns in vertical positions, the pressure which, in consequence of the weight of the particles vertically above is exerted in every direction by any particle of such filament, will be counteracted by the equal pressure of all the surrounding particles, so as to remain at rest, and act by its gravity on the particle vertically under it. And that the pressure exerted by the fluid against every part of the surface of the vessel containing it, will, while the fluid is at rest, be perpendicular to the surface; since, otherwise, the reaction of the surface could not entirely destroy that pressure, and a part of it would disturb that equilibrium which, by hypothesis, is the condition of the fluid in the vessel. The amount of that reaction is, of course, equal to the weight of a filament of fluid vertically above the point and extending to the upper surface of the fluid; or to the weight of any one of the neighbouring filaments comprehended between the upper surface and a horizontal plane passing through the said point. The pressure of all the particles in the upper surface of the fluid is evidently null.

It may, hence, also be proved, that the pressure on the base of any vessel containing a fluid, will be the same whatever be the form or position of the sides of the vessel, provided the fluid have always the same height above the base. For let A B D C (*fig.* 1) be a vertical section through a prismatical vessel; the pressure on any point *a* of the base is evidently equal to the weight of the vertical filament *b a*; that on any point *c* of the inclined side B D is the weight of the filament *c d*; and this last produces no effect on the base, because the lateral pressures of all the particles in every vertical filament, are counteracted by those of the particles in the neighbouring filaments. The same thing must be understood of all the water in the portion E B D. The pressure on any point *e* under the inclined side A C is equal to the weight of the filament *e f*, together with the pressure arising from the reaction of the side A C at *f*, in the vertical direction *f e*; and this reaction is, from what has been said, equal to the weight of a filament which may be supposed to exist above *f*, with a height equal to *f g*. Consequently, the pressure on A B, when the sides of the vessel are inclined to the horizon, will be equal to that upon the same base when the sides are in vertical positions. This is the foundation of the experiment usually exhibited in popular lectures, when columns of water of equal height, in cylindrical and conical vessels, having equal bases, but of course containing very different quantities of the fluid, are shown to be in equilibrio with one and the same weight applied to prevent the moveable bases from descending.

Fig. 1.

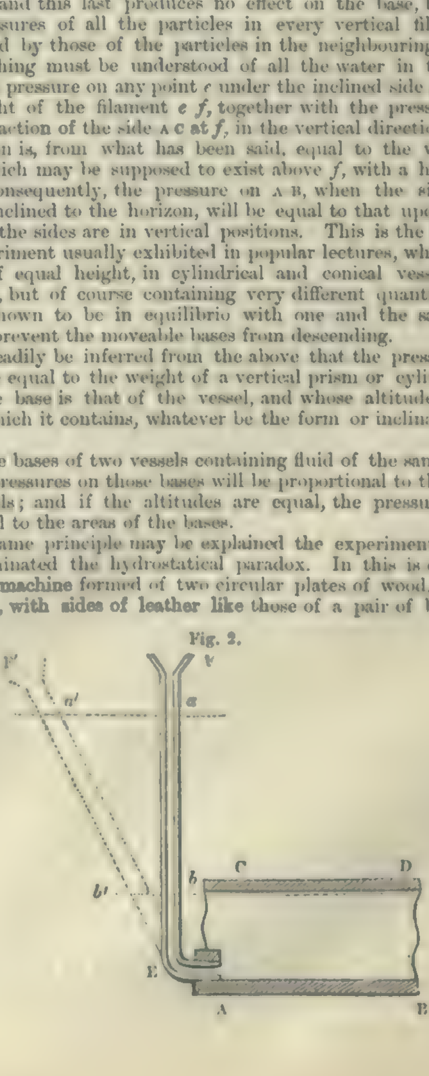


It may readily be inferred from the above that the pressure on the base will be equal to the weight of a vertical prism or cylinder of the fluid, whose base is that of the vessel, and whose altitude is that of the fluid which it contains, whatever be the form or inclination of the sides.

When the bases of two vessels containing fluid of the same kind are equal, the pressures on those bases will be proportional to the altitudes of the fluids; and if the altitudes are equal, the pressures will be proportional to the areas of the bases.

On the same principle may be explained the experiment which has been denominated the hydrostatical paradox. In this is employed a cylindrical machine formed of two circular plates of wood, as A B and C D (*fig.* 2), with sides of leather like those of a pair of bellows. A

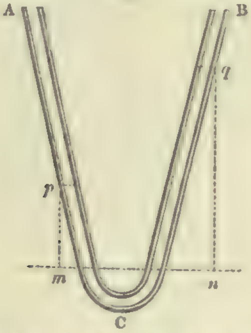
Fig. 2.



tube F E is inserted in an orifice near the bottom, and through this tube water is poured into the cylinder, till the boards A B and C D are at any distance asunder within the limits allowed by the leathern sides. Then, if any weight be placed on the board C D, it will cause the water to rise in the tube E F to a certain height, suppose a; and the weight of the small column $a\,b$ of water may be considered as holding in equilibrio the weight applied on C D; which will, in fact, be found to be equal to that of a cylinder of water whose base is the area of the board C D, and whose height is equal to $a\,b$.

If the tube E F were made to decline from the vertical so as to take any oblique position E F′; it would follow, since the pressure of a fluid by gravity depends on the vertical height only of the column, that the fluid in the tube, from the same pressure on C D, would rise till its upper surface is in a horizontal plane $a\,a'$ passing through a: and the weight of the column of fluid must be estimated by the area of the horizontal section at b' multiplied by the vertical height of a' above b'. Hence, also, any fluid in a bent tube A C B (*fig.* 3) will stand in each branch, the tube being open at both ends, at the same vertical height above C, the lowest point. Thus water, which is conveyed in pipes from a reservoir, will occupy all the bends of the pipes, and rise at the further extremity up to a horizontal plane passing through the surface of the water in the reservoir, provided no vertical bend be higher than that level.

Fig. 3.



The power produced by the Hydraulic Press depends on the principle exhibited in the above experiment; and this experiment is, at the same time, the proof of that equality of pressure which it has been said that the particles of a fluid exert in every direction.

The pressure exerted by a fluid against the whole side of a vessel containing it, or against a surface immersed in it, whether that side or surface be plane or curved, is equal to the weight of a column of the fluid having the surface pressed for a base, and the distance of the upper surface of the fluid from the centre of gravity of the former surface for its altitude. For let D B (*fig.* 1) be the position of the surface pressed, and let an indefinitely small area at c on that surface be represented by m, and be pressed by the weight of the filament $c\,d$ of fluid above it; then, since every part of the indefinitely small area may be supposed to be at the same vertical depth, which may be represented by n, it follows that the pressure on c will be proportional to $m\,n$. And the same thing will hold good with respect to every point in the surface D B. Therefore this surface may be conceived to be pressed by an infinite number of parallel forces, whose points of application are on the same surface, and whose intensities are represented by the products of the elementary areas into the distances of those areas from the upper surface C D of the fluid. But, by the theory of parallel forces in mechanics, the resultant of all those forces is a force whose intensity is represented by the sum of all the elementary areas (that is, the area of the surface pressed) multiplied into the distance of its point of application, that is, of the centre of gravity of the surface, from the same surface C D. By this theorem the pressure of water against the walls of reservoirs, lock-gates, &c., may be determined.

The pressure against one side of a cubical vessel filled with a fluid is equal to half the pressure upon the base; for the areas of the base and of each side are equal to one another, but the centre of gravity of the former is at a distance from the upper surface equal to the whole depth, and that of the latter at a distance equal to the half depth. It is shown moreover in treatises on hydrostatics, that if a hollow cone standing on its base be filled with a fluid, the pressure on the base will be equal to three times the weight of the fluid; that the pressure against the interior surface of a hollow sphere filled with a fluid is also three times the weight of the fluid. Again, if a vessel of any figure be full of a fluid, and have over every part of the sides and bottom a vertical filament of the fluid reaching to the upper surface, the whole pressure in a vertical direction on the bottom and sides of the vessel will be equal to the weight of all the fluid. Lastly, the pressure exerted on the sides of a vessel, estimated perpendicularly to the base, is equal to the weight of a rectangular prism of the fluid whose height is equal to that of the fluid, and whose base is a parallelogram, one side of which is equal to the height of the fluid, and the other to half the perimeter of the vessel. (Vince's 'Hydrostatics;' Gregory's 'Mechanics,' &c.)

It is of importance to determine the place of the centre of pressure against the side of a vessel filled with a fluid, or against a surface which is immersed in it; that is, to find the situation of a point in that surface, at which a force being applied in a contrary direction to that in which the fluid presses, the surface will be kept in equilibrio.

Let, for simplicity, the side or surface pressed be rectangular, and in a vertical position; let, also, b represent the breadth, and a the altitude of the surface, or depth of the fluid: then $\frac{1}{2}a$ will be the depth of the centre of gravity below the upper surface of the fluid. Now if x be the distance of any elementary area of the side below the same upper surface, such elementary area will be expressed by $b\,d\,x$; and the pressure of the fluid against it being proportional to the depth, will $= b\,x\,d\,x$. Then the tendency of that pressure to turn the side of the vessel round, about its upper extremity, which is supposed to be a horizontal line, will be $b\,x^2\,d\,x$; consequently the whole tendency of the fluid to turn the side round in that manner will be expressed by $\int b\,x^2\,d\,x$, which between the limits $x = 0$ at the top, and $x = a$ at the bottom, is equal to $\frac{1}{3}\,b\,a^3$. But, if P be the required place of the centre of pressure, and its distance from the upper surface of the fluid be represented by p, the tendency of the same pressure applied at P to turn the side about its upper extremity, will be $\frac{1}{2}\,a^2\,b\,p$ ($\frac{1}{2}\,a^2\,b$ being the horizontal pressure of the fluid against that side). Therefore we have $\frac{1}{3}\,a^3\,b = \frac{1}{2}\,a^2\,b\,p$, or $p = \frac{2}{3}\,a$; that is, the centre of pressure is at a distance from the upper surface equal to two-thirds of the depth of the vessel or fluid. And, by writers on hydrostatics, it is proved that, in all cases, when the surface pressed is symmetrical on each side of a line joining the centres of gravity and pressure, the latter coincides with the centre of percussion in mechanics.

When a triangle in a vertical position is immersed in a fluid so that its vertex coincides with the upper surface of the fluid and its base is horizontal, the distance of the centre of pressure from the vertex is equal to three-fourths of the perpendicular of the triangle. And when a circle is so placed in a fluid with its upper part just touching the surface, the distance of the centre of pressure from that part is equal to five-eighths of the diameter.

The equality of the pressures in every direction, at any point in a fluid mass, is the cause that, if a solid body be plunged in a fluid, the pressure of the fluid immediately under it will tend to raise the body upwards with a force equal to the weight of the fluid displaced. But the weight of the body is a force acting vertically from above downwards; and, consequently, in an opposite direction to that caused by the reaction of the water. Since therefore the volumes of the body and of the displaced water are equal to one another; if their weights or densities should be equal, the body would remain in equilibrio in whatever situation it were placed in the fluid. But should these weights or densities be unequal, the body would make an effort to ascend or descend, according as its density is less or greater than that of the fluid; and, in order to counteract these tendencies, it would be necessary to use a force equal to the difference between the weight of the body and of the displaced fluid. Hence, if a solid body be weighed in a fluid, it will be found that its weight, compared with that of the same body in vacuo, will be less than in the latter case by the weight of an equal volume of the fluid; and, consequently, when a body is weighed in a fluid, as water or air, the true weight, or that which would be obtained in vacuo, will be found by adding to the observed weight that of an equal volume of the fluid.

When a body floats in a fluid, in order to bring its upper surface to coincide with that of the fluid, it must evidently be loaded with a weight equal to the difference between the weight of the body or of the displaced fluid, and the weight of a volume of the fluid equal to that of the whole body. The weight which a floating body will thus bear is denominated the buoyancy of the body; and on the principle here stated depend the common rules for finding the buoyancy of rafts, vessels, &c.

If a solid body float in equilibrio in a fluid, the centres of gravity of the body and of the displaced fluid must evidently be in one vertical line; otherwise the upward action of the fluid below, which necessarily has its resultant in a vertical line passing through the centre of gravity of the place occupied by the body, would produce in the latter a rotatory motion contrary to the hypothesis. This circumstance has given rise to three denominations respecting the equilibrium of floating bodies. First, if the centre of gravity of the body should be below that of the displaced fluid, the body is said to possess a stable or firm equilibrium; so that if any derangement should take place from accidental causes, the body would, after a few oscillations, recover its former position. If the centre of gravity is above that of the displaced fluid, the body is in circumstances similar to those of a cone when placed on its vertex, that is, it is liable to be immediately overturned; and hence the body is said to float with a tottering or unstable equilibrium. And if the said centres should exactly coincide, the body would float in any position whatever: this is denominated an equilibrium of indifference. The first case is that of a cylinder whose axis is less than the diameter of its base; the second is that of a cylinder whose axis is greater; and the last is that of a homogeneous sphere.

The absolute weight of a given volume of any solid or fluid body is called its specific gravity. In this country, for convenience, it is customary to consider one cubic foot as the given volume, and to express the weight in avoirdupois ounces: thus the weight of a cubic foot of rain water being 1000 ounces, and that of a cubic foot of cast-iron being 7207 ounces, those numbers are used to denote the specific gravities of the bodies. From this definition it follows that, when the volumes of two bodies are equal, their specific gravities will be proportional to their weights: when the weights are equal, the specific gravities are inversely proportional to the volumes; and, in general, the weights of bodies vary in a ratio compounded of their volumes and specific gravities.

It may hence be easily shown that when two fluids of different specific gravities, as water and mercury, are in equilibrio in a bent tube, the vertical altitudes of the columns above the horizontal plane of junction will be inversely proportional to their specific gravities. For, let m n (*fig.* 3) be a line in the plane of junction; then the area of the section at m being common to both fluids, the bases of the columns in the two branches may be considered as equal to one another. Now, if the vertical altitude of the column m p be represented by a, and that of n q by A, the specific gravity of the fluid in m p by S, and that in n q by s; then the weights of the columns, or rather the pressures on every point of their bases, at m and n may be expressed by a S and A s; and in the case of equilibrium these terms are equal to one another: therefore we have A : a : : S : s.

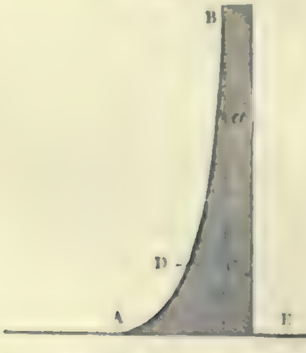
The specific gravity of a solid body is readily found by means of the hydrostatical balance, an instrument which differs in no respect from a common balance, except in being made with greater delicacy. It is customary to weigh the body both in air and in vacuo; from whence may be obtained the ratio between the density of the body and that of the fluid in which it is weighed. [Specific Gravity.]

The specific gravity of a fluid may be found from the following proposition: let $a+b$ be the volume of a body which will float in the fluid, b being that of the immersed part; let also the specific gravities of the body and fluid be represented by s and s' respectively. We have then the weight of the body $=(a+b)\,s$, and that of the displaced fluid $=b\,s'$; but these weights are equal to one another: therefore, $b:(a+b)::s:s'$. Consequently, the specific gravity of the solid body being supposed to be known, we have that of the fluid, after making a correction on account of the loss of weight in air. On the principle explained in this proposition is founded the construction of the **Hydrometer**, by which the qualities of liquors are usually determined.

By means of the specific gravity of bodies may be ascertained the quantities of the different materials which enter into any compound body. Thus, let w and w' represent the weights of a mixed metal in air, or vacuo, and water respectively, s and s' the known specific gravities of the two metals in the mixture, and let x be the weight in air or vacuo of the heavier metal. Then $\frac{x}{s}=$ the weight of water which would be displaced by x; $\frac{w-x}{s'}=$ the weight which would be displaced by the lighter metal; and we shall have $w'=\frac{x}{s}+\frac{w-x}{s'}$; whence $x=\frac{s\,(w-w's')}{s-s'}$, and $w-x$ (= the weight of the lighter metal) $=\frac{s'\,(w'-w\,s)}{s-s'}$.

It has been shown that the pressure of a fluid against any point in an upright wall, or in the side of a vessel containing it, is proportional to the depth of that point below the upper surface of the fluid; but, in determining the form and dimensions of a retaining wall which shall be equally strong in every part of its height, it will be necessary to consider that the horizontal pressure of the fluid at any point, as a (*fig.* 4) (B A E representing a vertical section through such a wall), tends to overturn or fracture the wall at every other point, as C. Now, let B $a=x$, and let the depth of an elementary portion of the wall at a be represented by $d\,x$; then, if B C be represented by b, we shall have C $a=b-x$, and $(b-x)\,x\,d\,x$ will express the force of the water on an elementary area at a to turn the wall about C: consequently, $\int(b-x)\,x\,d\,x$, between $x=0$ and $x=b$, will express the sum of all the forces of the water above C to turn the wall about the latter point. But the integral between those limits is equal to $\frac{1}{6}\,b^3$: therefore the tendency of the fluid to fracture the wall at any point, as C, is proportional to the cube of the distance of that point from the upper surface of the fluid. The strength of the wall to resist transverse pressure in the direction of its thickness is, by mechanics, proportional to the square of that thickness; that is, proportional to C D^2. Therefore, in order that the wall may be equally strong in every part, the form of a vertical section should be such that the squares of the horizontal ordinates, as C D, are proportional to the cubes of their vertical depths from the top. This is a property of the semi-cubical parabola, and the exterior or interior surface of the wall should have that figure. Agreeably to this principle also the thickness of tubes containing columns of fluid in vertical positions should increase from top to bottom, according to the same law.

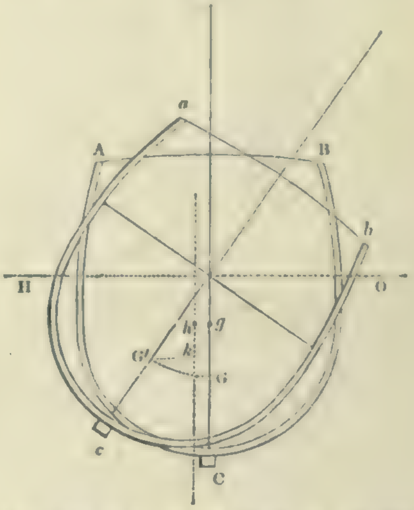
Fig. 4.



This article may be concluded by an indication of the principles on which the stability of ships or other vessels on the water may be determined.

Let A B C (*fig.* 5) represent a vertical section through the centre of gravity G of a ship, and let H O be the surface of the water; let also g be the centre of gravity of the immersed part, while the plane of the masts is vertical. Now, by the action of the wind or otherwise, let the ship be inclined so as to take the position $a\,b\,c$; the centre of gravity of the immersed part and of the displaced water will then be removed to h, and that of the ship to G′. Draw a vertical line through h, and let fall upon it the perpendicular G′ k; then the stability of the vessel, or the force by which it resists the effort of the wind to overturn it, is expressed by the product of the upward pressure of the water (or the weight of the vessel) acting in the vertical line $k\,h$ into the length G′ k of the lever, whose fulcrum is G′. And, that an equilibrium may subsist, this expression must be at least equal to the product of the force of the wind acting against the sails or hull into the distance of the centre of pressure, or *metacentre*, from the centre of gravity of the ship.

Fig. 5.



Hence it is, that the keel and bottom of a vessel must be made so much stronger, the deeper the vessel sinks. Suppose a vessel sinks 16½ feet when loaded; then the bottom must be able to resist a pressure of 7¼ lbs. on the square inch, that is, the weight of a cylinder of water 16½ feet long, and 1 inch in section. Hence, if a leak should spring in such a vessel, a weight of 7¼ lbs. per square inch would be required, to keep a plank, thrown across the hole, from being forced upwards.

HYDROSULPHOCYANIC ACID. [Cyanogen.]

HYDROSULPHURIC ACID. [Sulphur; *Sulphuretted Hydrogen.*]

HYDROTHIONIC ACID. Synonymous with *Sulphuretted Hydrogen.* [Sulphur.]

HYDROTHO'RAX (from ὕδωρ, water, and θώραξ, the chest), dropsy of the chest, is a term applied to express the existence of a collection of serous fluid in the cavity of the pleura.

This collection may take place in consequence of inflammation of the pleura, which, like inflammation of other serous membranes, terminates in effusion; or it may result from the causes of general dropsy,—namely, some obstacle to the circulation through the heart, or organic disease of the kidney. When it arises from the former cause it is merely a symptom of pleurisy. In some cases of pleurisy, however, in which pain is absent, and in which fever does not exist, or is slight, this effusion and the difficulty of breathing to which it gives rise constitute almost the only symptoms of the disease. Abundant effusions of this kind, unattended by pain or fever, sometimes take place very rapidly, especially in old persons and in adults in a cachectic condition.

When hydrothorax results from inflammation of the pleura, it generally exists on one side only of the chest. When it is a consequence of obstacle to the circulation through the heart, or of organic disease of the kidney, it is generally double, although the effusions into the two pleural cavities may not take place quite simultaneously. In the latter case, also, hydrothorax is found in connection with general dropsy. At first there is œdema of the lower extremities; this œdema gradually extends to the integuments of the trunk, to the arms, and even to the face; and, subsequently, serous fluid is effused into the cavities of the pleura, giving rise to hydrothorax, and into those of the pericardium and peritoneum.

A collection of fluid in the cavity of the pleura may be detected by physical signs: a dulness on percussion, and, when the effusion is moderate, a diminution of the respiratory murmur, and the presence of ægophony, on the affected side. If the effusion be so considerable as entirely to prevent the expansion of the lung, there is a total absence of ægophony or of any respiratory murmur on that side, whatever be the force with which inspiration is made, while on the opposite side the respiratory murmur is unusually audible.

When one side only is affected, the patient generally lies on that side; when the effusion is double, he lies on his back; or, which is the case when the effusion is considerable, he can breathe in the erect position only. The difficulty of breathing is generally greater in proportion to the rapidity with which the fluid is effused. [PLEURITIS.]

HYGIEIA (Ὑγίεια), the goddess of health, called also Salus by the Romans, was the daughter of Æsculapius, with whom she was frequently associated in worship, both by the Greeks and Romans. She was worshipped as the goddess of both mental and bodily health, and in some of her attributes resembled Athena, one of whose titles was Athena Hygieia. Representations of Hygieia, both alone and with her father, are very numerous in ancient art. She appears always as a virgin of beautiful form, and pleasing expression, and is clad in a long full robe. Most frequently, she is giving drink to a serpent from a patera which she holds in her left hand. The annexed cut is from a terra-cotta bas-relief in the British Museum.

Hygieia from the British Museum.

HYGRO'METER (ὑγρός, moist, and μέτρον, measure). In physical experiments it sometimes becomes necessary to ascertain the quantity of aqueous vapour contained in the atmosphere or other aëriform fluid under examination. To attain this object several instruments called hygrometers have been invented, and are known by the names of their authors, as De Luc's, De Saussure's, &c. These for the most part rest upon one common principle, the diminution of bulk which takes place in organic tissues consequent upon the abstraction of moisture. Thus De Luc employed a thin slip of whalebone, the contractions of which indicated the variations of moisture; and De Saussure had recourse to a human hair, by means of which he constructed a far more delicate instrument; but this was exceedingly liable to derangement, and unless prepared with extraordinary care was uncertain. All of these, however, were nearly superseded by the hygrometer invented by the late Mr. Daniell, professor of chemistry at King's College, London, first described by that gentleman in 1819, in the 8th volume of the 'Quarterly Journal of Science;' subsequently in his 'Meteorological Essays,' and in his posthumous work on 'Meteorology.' It consists of two thin glass balls one inch and a quarter in diameter, connected by a glass tube about seven inches in length. The tube is bent in two places at right angles so as to form three arms of unequal length, the longest of which contains a small thermometer, whose bulb descends into the lower of the two glass balls. This ball, after being filled about two-thirds with ether, is placed over a spirit-lamp until the vapour of the ether has expelled the contained air through a capillary tube which is left open for the purpose, and afterwards hermetically sealed. The other ball is then covered with a piece of muslin, and the instrument thus adjusted is placed upon a stand, to which is attached a small thermometer indicating the temperature of the external air. When about to be used a small portion of ether is poured upon the muslin, which, by evaporating, lowers the temperature of the glass ball, and thereby occasions a rapid condensation of the ethereal vapour contained within the instrument. The condensation of the vapour within the tube produces a continuous evaporation from the surface of the ether in the lower ball, by which the temperature of the included ether is continually reduced until a deposit of moisture from the surrounding atmosphere is observed to take place upon the exterior of the glass. At this instant the inner thermometer, which always indicates the temperature of the ether, is observed, and thus the dew point, or that at which the precipitation of atmospheric moisture takes place, is determined with considerable accuracy. Having ascertained the dew point, and likewise the temperature of the external air, the actual quantity of moisture contained in a cubic foot of air will readily be found from the formula,

$$\text{Weight in grains} = \frac{5656{\cdot}2}{448 + t} \times p,$$

where t denotes the temperature of the external air, and p the elasticity of aqueous vapour at the temperature indicated by the interior thermometer. The value of p for every degree of the thermometer is given in Mr. Dalton's tables of the expansive force of steam. ('Manchester Memoirs,' v. 559.)

But this instrument, so excellent in theory, is very costly on account of its great consumption of ether, and is scarcely useable in hot climates, owing to the difficulty of preserving that liquid. It has also been objected to by competent authority, because *an experiment* has necessarily to be made to obtain an observation. At the Royal Observatory at Greenwich, however, it appears to have been employed for the determination of the dew-point from the commencement of the meteorological observations in the year 1840 until the end of 1847, since which, to the present time, that element has been exclusively inferred in those observations from the simultaneous reading of two thermometers, the bulb of the one being dry and the other wet, agreeably to the method which has now almost universally superseded every other, and which is explained in the next article.

Under the head DEW, some experiments of Dr. Wells and of Mr. Glaisher have been noticed, having an important bearing upon the use of many inorganic as well as organic substances for hygrometrical purposes, as well as upon the necessity of screening hygrometrical apparatus from the effects of its own nocturnal radiation.

HYGROMETRY is that part of natural philosophy which relates to the determination of the humidity of bodies, particularly of the atmosphere: it comprehends also the theory of the instruments noticed in the preceding article, which have been invented for the purpose of ascertaining the quantity of water contained in a given volume of air.

The experiments of Dr. Dalton have proved that the water received from the earth is not dissolved in the atmosphere, and that it exists there in the state of vapour, and forming, statically, a distinct atmosphere from that of the air, though coexisting with it in the same space. That philosopher discovered also, that the quantity of vapour contained in a portion of the atmosphere depends greatly upon the temperature of the latter, and that it is very variable even when the temperature is constant. He ascertained moreover that when a quantity of aqueous vapour at a given temperature is diffused through any space, it will support the same external pressure, whether previously that space had been void or occupied by air. On these principles are founded the methods which have been used for determining the absolute quantity of moisture in a given volume of air by means of the hygrometer: the requisite data being the elasticities of aqueous vapour at different temperatures, and the corresponding indications of the instrument.

The tension or elasticity of watery vapour corresponding to every degree of Fahrenheit's thermometer, from zero to the point of boiling water (measured by the height in inches of the column of mercury which the vapour will support when the density of the atmosphere is represented by 30 inches), has been determined by Drs. Dalton and Ure, who for this purpose introduced a small quantity of water into the vacuum of a barometer, and observed how much, at different temperatures, the vapour arising from it depressed the column of mercury; and tables of such tensions are published in the fifth volume of the 'Manchester Memoirs,' and the 'Philosophical Transactions' for 1818.

Previously to stating the manner of determining the relation between the indications of an hygrometer and the state of aqueous vapour with respect to tension, it will be proper to notice the following circumstances:—When an hygrometer, like that of Saussure or De Luc is introduced into a close vessel, or into any part of space fully saturated with aqueous vapour, it is observed that, whatever be the temperature, the index points to the same degree; from which it may be inferred that equal quantities of vapour have been absorbed by the material (hair or whalebone) of which the instrument consists, notwithstanding the difference of temperature. In fact the vapour in the vessel, or space, is in such a state that the presence of a material having the least possible attraction for water is sufficient to produce a precipitation of the latter: the hygroscopic material has an attraction for water, and thus it absorbs that which is precipitated. But the quantity absorbed is so small as not to diminish sensibly the elasticity of the vapour in the vessel; and therefore the absorption continues to the full extent of the attraction of the material: the quantity thus absorbed is necessarily constant, unless the attraction undergo some change by a change of temperature; but experience proves that the attraction of the material is not sensibly altered by such change within the usual limits of the thermometric scale.

When the vessel into which the hygrometer is introduced is not completely saturated with water, the quantity of water absorbed by the hygroscopic material is limited by the power of the latter to absorb the precipitated moisture: that power diminishes in proportion to the quantity received, so that the attraction of the material for water ceases to act when it is equivalent to the pressure which the vapour can support without becoming liquid; and the elongation of the hair or whalebone then ceases, or the index remains stationary on the scale.

In order, then, to determine the law according to which the attraction of the hygroscopic material for water diminishes as the precipitated water is absorbed by it, or, in other words, to find on the scale of the hygrometer a number of points corresponding to any given elasticities of the vapour, Gay Lussac put water into a vessel of glass; and, having determined the elasticity of the vapour arising from it, he suspended from the upper part of the vessel a delicate hygrometer of the kind invented by Saussure. The vessel was then closely covered, so that there might be no communication between the vapour within and the external air; when, after a short time, the index of the hygrometer became stationary at a certain point on the circumference of the graduated ring which served as a scale; this point thus became an indication of the elasticity of the vapour. Experiments of the like kind being made with vapour of equal temperature, but in different states of elasticity, between those which correspond to extreme dryness and complete saturation, there were obtained so many points on the scale of the instrument as indications of the elasticities of the vapour.

From the results of these experiments, M. Biot found, by interpolation, a table of the elasticities of vapour for every degree of Saussure's hygrometer, the temperature being 10° of the centigrade thermometer (50° Fahr.). He also formed a table showing the degrees of the hygrometer corresponding to every degree of elasticity. The extremes of dryness and moisture on the scale, and also the corresponding extremes of elasticity, were indicated respectively by 0 and 100 (Biot, 'Traité de Physique,' liv. i. ch. 13); but the elasticities or tensions would be more conveniently expressed in terms of the elasticity at the point of complete saturation, which is then represented by unity.

The numbers in the table are formed from the observed tensions at a constant temperature equal to 50° (Fahr.); and it might be supposed, since the index of the hygrometer stands constantly at 100° when the material is acted on by vapour in the state of maximum tension whatever be the temperature, that the index should stand at one point on the scale when the tensions of the vapour have the same proportion to the maximum tension at their respective temperatures: this supposition is not quite correct; but it may be presumed that in using Biot's table for temperatures differing from 50° Fahr., the error in the tensions will not be considerable.

Gay Lussac having proved that vapours, whether those of pure water or those of different liquids intermixed, while they retain their character of elasticity, suffer the same variations of volume by variations of pressure as are suffered by fluids, which are permanently elastic within ordinary ranges of temperature and pressure, determined, by subsequent experiments, the volumes of the vapour produced by a given weight of water at given temperatures and under given atmospherical pressures; and thus, consequently, obtained the quantity of moisture in a given volume of vapour. The results of his experiments were reduced to a formula by Biot; and subsequently, with certain modifications, to one in English weights and measures by Dr. Anderson, the writer of the article on Hygrometry in the 'Edinburgh Encyclopædia.' This formula is

$$G = \frac{10953\,B\,.\,F}{447{\cdot}4 + t};$$

in which G is, in grains, the quantity of moisture in a cubic inch of vapour at the temperature represented by t (Fahrenheit's scale), F is the elastic force of the vapour at the same temperature, and B is the height of the barometrical column in inches at the time of the experiment.' It agrees nearly with that which was obtained by Dalton from experiments on the state of the thermometer at the dew-point, the height of the mercurial column in that result being 30 inches. From this formula, the temperature t being 50° (Fahr.), $B = 30$ inches, and $F = 0{\cdot}375$ (from Dalton's table of the elastic force of vapour corresponding to that temperature and that density of the air), we have $G = {\cdot}002477$, the grains of moisture in a cubic inch of the vapour.

The value of G being thus found for any given states of the barometer and thermometer; the weight of moisture, in grains, in a cubic inch of air of the like density and temperature, and corresponding to any observed degree of Saussure's hygrometer may be obtained on multiplying that value by the number in Biot's table corresponding to the observed degree and dividing the product by 100; this division must be made because, in that table, 100 represents the elasticity of the vapour when in the state of complete saturation.

The extreme points on the scale of an hygrometer acting by the elongation of a material, like those of Saussure and De Luc, may be found in the following manner: the instrument is to be placed under a receiver in which is a certain quantity of dry caustic alkali; when, after a time, the material will contract in length as much as its nature will permit; the point on the scale at which the index stands is that of extreme dryness, and constitutes the zero point. The instrument may then be placed in water, or in a receiver filled with vapour completely saturated with moisture, when the material will expand to the greatest extent possible: the place of the index is then to be considered as the point of extreme humidity, and is usually indicated by 100. The employment of organic substances in hygrometry, has however, been long since almost disused, for exact purposes.

Leslie's hygrometer consists of a glass tube bent so as to form two equal branches parallel to one another, and each terminating with a hollow ball into which is introduced sulphuric acid, coloured. One of the balls is covered with cambric, which is kept constantly moist by water from a neighbouring vessel; and the evaporation of the water, by cooling that ball, allows the air in the other, by its superior elasticity, to depress the acid in the tube below and force it to rise in the other. The degree of evaporation depends partly on the temperature, and partly on the state of the surrounding atmosphere with respect to humidity; and hence the depression of the acid in the tube, being measured by a convenient scale, affords an indication of the relative dryness of the air. In order to determine the absolute quantity of moisture in a given volume of the atmosphere by the state of his hygrometer, Leslie, having found from some experiments that the capacity of air for caloric was $\frac{3}{8}$ of that of water, and having ascertained that the quantity of caloric necessary to convert a given volume of water into vapour was expressed by 6000 degrees of his instrument; concluded that the same quantity of caloric would raise an equal volume of air to a temperature expressed by $\frac{8}{3} \times 6000$, or 16,000 degrees of the instrument; and consequently that, at the temperature of the wet ball, atmospheric air contains a quantity of moisture equal to $\frac{1}{16000}$ part of its weight for each degree; the scale between the points of extreme dryness and extreme moisture being divided into one thousand parts. (Treatise 'On the Relations of Air to Heat and Moisture.')

From the fact that the elastic forces of pure vapour and of vapours mixed with atmospheric air are equal to one another, the expansion which air undergoes in consequence of being saturated with moisture may be found. For if V represent a given volume of dry air, V' the volume when saturated, and B, in inches, the height of the barometrical column; then the elastic force of the air, under the increased volume V' is $\frac{V.B}{V'}$. Now F representing the elastic force of the vapour in inches of mercury, which, for the given temperature, may be found from Dalton's table, the sum of the elastic forces of the air and vapour will be expressed by $F + \frac{V.B}{V'}$; and this being made equal to B, the pressure of the atmosphere, the value of $V' - V$ may be found. Making $V = 1$, that value expresses the expansion in a fractional part of the volume of dry air.

At any place on the surface of the earth, the mean temperature at which moisture begins to form in the atmosphere may be found from Dalton's formula $E = \frac{1}{30} M (F - F')$, in which E is the number of grains evaporated in one minute from the surface of water in a cylindrical vessel 6 inches in diameter and 1 inch deep, F is the elastic force of vapour in the atmosphere at a given temperature, which may be the mean annual temperature at the place (50° Fahr., for Great Britain), and F' the elastic force exerted at the time that the moisture begins to form: M is, in grains, the evaporating force in an atmosphere supposed to be perfectly dry; and Dalton has given a table of such forces for different temperatures, the atmosphere being at rest, in gentle, and in violent motion. In the table, the temperature being 212°, the height of the barometrical column 30 inches, and the wind blowing moderately, the value of M is 154; and substituting this value in the formula, we have $F' = F - \frac{1}{5} E$.

The mean annual evaporation in Great Britain is ·0000456 inches or ·01155 grains per minute: this last number being multiplied by the area of a circle 6 inches in diameter, gives 0·3236 grains per minute ($= E$) from a vessel of that magnitude; hence $F' = F - 0{\cdot}0647$. But, by Dalton's table, the elastic force (F) of vapour at a temperature equal to 50° is expressed by 0·375, in inches of mercury; hence $F' = {\cdot}3103$ inches. Substituting in the above formula for G this value of F' in place of F, and 30 inches for B, we get ·00205 for the number of grains of moisture in a cubic inch of air corresponding to the elasticity F′. To this number corresponds the temperature 44° 16′; which may be found by inspection in a table formed to contain the values of G for different degrees of temperature.

The subject of hygrometry, including the principle and construction of the numerous instruments which have been employed for the purpose of determining the amount and tension of aqueous vapour in the air under various circumstances, has formed, during a century past, so considerable a part of meteorology and experimental physics—especially from the time of the publication of a celebrated paper by De Luc, in the 'Philosophical Transactions' for 1792—and is so intimately connected also with the history of the progress of science in that period, that we have thought fit to retain, with a few slight insertions and alterations, the preceding portion of this article as it originally appeared in the first supplement to the 'Penny Cyclopædia,' in the year 1846. But it has already been remarked, in the article DEW-POINT, that for the determination of that critical temperature and its depression, the *indicia* of all hygrometry, the simultaneous observation of the dry-bulb and the wet-bulb thermometer is now almost universally adopted, according to a method we shall proceed to describe.

In this method the bulb of the wet thermometer, as described by Mr. Glaisher in the Introduction to the 'Greenwich Meteorological Observations' for 1847, is covered with a piece of fine muslin; immediately under it is placed a small cistern of rain-water. A piece of cotton lamp-wick is connected with the muslin, and its end dips into the cistern of water; the water ascends the wick by capillary action, and keeps the muslin on the thermometer constantly wet. In frosty weather the muslin is moistened for a sufficient length of time before each observation, in order to allow the water to have become frozen, and the evaporation from the surface of the ice to have commenced, at the time of making the observation; the evaporation of the ice will depress the temperature, as if it had remained liquid. These thermometers should be placed and observed in such a locality as shall afford the best chance for procuring a fair indication of the moisture of the general atmosphere, and by no means in any confined or ill-ventilated situation, or where many persons habitually congregate, or which, from any other cause, is usually or periodically damp. The whole apparatus should be protected by a cap of wire-work to defend it from injury, which, however, if it interfere with the readings of the thermometer, should be removed a quarter of an hour before the observation. At night the thermometers should be completely screened from the sky, so as to annihilate all loss of heat by upward radiation.

The dry thermometer is to be first read, and in reading it, as in all readings of such instruments, the observer should avoid touching, breathing on, or in any way warming it by the near approach of his person; and in night observations particular care should be taken not to heat it by approach of the light. The quicker the reading is done the better. The observer will then enter the simple readings, but at the head of each column place the zero *correction* (with its proper sign) required for its thermometer, and leave a blank column for the hygrometric depression, or depression of the dew-point, in calculating which subsequently the zero must be *applied*.

The reduction of the observations to derive the *elastic force of vapour at the dew-point* is effected by the formulæ of Dr. Apjohn:—

$$F = f - \frac{d}{88} \cdot \frac{h}{30} \cdot \cdot \cdot \cdot (a); \; F = f - \frac{d}{96} \cdot \frac{h}{30} \cdot \cdot \cdot \cdot (b).$$

(*a*) To be used when the reading of the wet thermometer is above 32°, and (*b*) when below. In these formulæ *d* is the hygrometric depression, *h* the height of the barometer, *f* the elastic force of vapour for the temperature shown by the wet thermometer, to be taken from an appropriate table of the elastic force of aqueous vapour for every degree of temperature through a sufficient range, and F the elastic force of vapour at the dew-point, which (all other quantities being known) these formulæ enable us to calculate. If, with F so calculated the same table be entered under the column of force of vapour, the corresponding *temperature* is the dew-point, which, however, is not wanted to be known except for objects distinct from that of this process of hygrometry. In all these calculations Mr. Glaisher's 'Hygrometrical Tables,' which form a separate publication (second edition), will be found of great value, including as they do all the requisite data and corrections.

Among these tables, which were originally published in the 'Introductions to the Greenwich Meteorological Observations,' is one which shows the elastic force of vapour, in inches of mercury, for every tenth of a degree, from 0° to 90°, calculated from the experiments of Dalton, and those of the late Dr. Ure, noticed in the preceding part of this article. The history of this table we shall briefly state, as it involves the verification of the quantities now generally employed in the reduction of hygrometrical observations, as well as that by implication of Dr. Apjohn's formulæ already given. Before deciding upon the use of the table, many comparisons were made by Mr. Glaisher between the observed dew-point, and that deduced from the observed temperature of evaporation by means of the formulæ of Dr. Apjohn (originally published in the 'Proceedings of the Royal Irish Academy,' for 1840), using the values of the elastic force of vapour as given in the 'Report of the Committee of Physics including Meteorology' of the Royal Society of London, 1840; and also between it and that deduced from the values of that force and the formulæ given by Professor Kæmtz, in his work on Meteorology. It was found in this comparison that the errors of the inferred dew-points were considerable with both sets of tables. Similar comparisons were made, using the table in question, and the errors were found to be always small. Dr. Apjohn's formulæ, combined with it, gave results in close accordance with direct observations of the dew-point. It follows therefore that it represents with considerable accuracy, the relation between the tension and the temperature of steam.

We must not conclude, however, while on this branch of the subject, without directing the attention of the reader and hygrometrical observer, to the following remarks of Sir John F. W. Herschel: "The discussion respecting the formulæ and coefficients of reduction of observations of this nature can hardly be regarded as satisfactorily terminated; and it cannot be denied that great difficulty still subsists in determining, by any mere reading of instruments, the exact hygrometric state of the air. In the absence of direct observation of the Dew Point, the actual absorption and weighing of the water contained in a given volume of air seems to be the only method free from theoretical objection, and it might not be very difficult to contrive a portable apparatus for this purpose." 'Meteorology,' in 'Admiralty Manual of Scientific Enquiry,' 3rd edit., 1859, p. 134, note.

The 'Greenwich Magnetical and Meteorological Observations,' for the years subsequent to 1847, have appeared in an Appendix (also issued separately), to the annual volume of 'Astronomical Observations made at the Royal Observatory.' The hygrometrical deductions are stated for each month among the results of the ordinary meteorological observations, under the head of 'Humidity of the Air,' and consist of the temperature of the dew point, the elastic force of vapour, the weight of vapour in a cubic foot of air, the degree of humidity, and the weight of a cubic foot of air. From August 24, 1856, hourly observations have been made once in every week during twenty-four hours, the hygrometrical deductions from which, stated for each hour, include also that of the vapour required to saturate a cubic foot of air. Those deductions, together with the other meteorological elements, are further given in the form of monthly means. It is explained in the 'Introduction to the Observations for 1857' (the latest which have been published) that, the dew-point having been inferred exclusively (as noted in the preceding article) from simultaneous observations of the dry-bulb and the wet-bulb thermometers; in order to find the difference between the reading of the former and the dew-point, the difference between the dry-bulb and the wet-bulb readings has been multiplied by a factor taken from the following table, which has been deduced by Mr. Glaisher from the comparison of all the simultaneous readings of the dry-bulb, wet-bulb, and dew-point thermometers from the year 1840 to the end of the year 1854. The dew-point having been thus found for each individual observation, the mean has been taken for each day (as defined from midnight to midnight), and this mean is corrected by application of the elements in Mr. Glaisher's paper 'On the corrections to be applied to the Monthly Means of Meteorological Observations taken at any hour, to convert them into Mean Monthly Values;' 'Phil. Trans.' 1848, part i.

TABLE OF FACTORS BY WHICH THE DIFFERENCE OF READINGS OF THE DRY-BULB AND WET-BULB THERMOMETERS IS TO BE MULTIPLIED, IN ORDER TO PRODUCE THE DIFFERENCE BETWEEN THE READINGS OF THE DRY-BULB AND DEW-POINT THERMOMETERS.

(CLOUD; DEW-POINT; DEW; EVAPORATION; HAIL; HOAR-FROST; METEOROLOGY; RAIN; SNOW; VAPOUR.)

HYMEN, or HYMENÆUS, the god of marriage, was the son of Apollo and a muse. In very early legends he was described as a mortal of extreme beauty, who delivered from captivity some Attic virgins who had been carried to Eleusis by Pelasgian pirates. For this service he was rewarded with a maiden of whom he was deeply enamoured; and on account of his conduct, and the happiness of his marriage, he was invoked in bridal songs, thence called hymeneal songs. But several other legends are related, which account for his apotheosis in a somewhat different manner. In ancient art he is represented as a tall and elegant, but somewhat effeminate youth—a larger and more serious Eros. He usually carries in his hand the bridal torch, and sometimes wears on his head, or around his neck, a wreath of flowers.

HYMN (ὕμνος), a song of praise and adoration, in honour of a Deity, and by the Hebrews, as well as the Greeks, accompanied on some musical instrument. The *Te Deum* and *Benedictus* are, in our liturgy, both called hymns: the former is supposed to have been written by St. Ambrose; though St. Hilary, bishop of Poitiers, is said to have been the first who composed hymns for the church. To Prudentius is ascribed most of those which appear in the Roman breviary. The hymn should be a song of joy, not of lamentation, as is too often the case in the present day. Such was the opinion of St. Isidore, who gave to the song of complaint and sorrow the name of *threna*, from threnos (θρῆνος), "lamentation."

The term is now applied to any short religious poem sung in places of public worship, not being a version of a psalm, or taken directly from any of the canonical books of Scripture.

HYOCHOLALIC ACID ($C_{50}H_{40}O_{8}$). A peculiar crystalline acid, produced along with sugar of gelatin by the action of potash upon hyocholic acid.

HYOCHOLIC ACID ($C_{54}H_{43}NO_{10}$). This acid, in combination with soda, constitutes the chief portion of the bile of the pig. It is a white resinous body, fusible in hot water, and then presenting a silky appearance. It is very slightly soluble in water, by which it is distinguished from cholic acid. It gives insoluble precipitates with lime and baryta.

HYOCHOLOIDIC ACID. [HYODYSLYSIN.]

HYODYSLYSIN ($C_{50}H_{38}O_{6}$). An homologue of dyslysin, produced by the action of boiling hydrochloric acid upon hyocholic acid. It is insoluble in water, ammonia, and potash, tolerably soluble in ether, and but slightly soluble in alcohol. Its formation is preceded by that of a peculiar resinous acid, termed *hyocholöidic acid*.

HYOSCYAMINE, *Hyoscyama*, the active and alkaline principle of the *Hyoscyamus niger* and other varieties of henbane, from which it is obtained by a very complex and tedious process.

The properties of hyoscyamine are:—It crystallises in stellated groups, which have a silky lustre; and it is often obtained in the state of a colourless, viscid, adhesive mass. When perfectly dry it is inodorous; but when moist, especially if impure, it has a disagreeable stupefying smell, resembling that of tobacco. When anhydrous, hyoscyamine has not an alkaline reaction; but when mixed with water it has, on the contrary, very permanently alkaline properties. It is not volatile at common temperatures, and undergoes no change by exposure to the air. It melts at a low temperature, flowing like oil, and is volatilised at a high temperature; a large portion of it is then decomposed, becoming carbonised and yielding ammoniacal vapour. It is also partly volatilised by the vapour of boiling water, and communicates to the distilled water the properties of a narcotic poison. It is readily soluble in water, and iodine added to the solution gives a kermes-coloured precipitate; tincture of galls gives a white precipitate; chloride of gold precipitates whitish flocculi; solution of chloride of platinum gives no precipitate whatever. It dissolves also in alcohol and in ether.

Hyoscyamine burns with a sooty flame; concentrated nitric acid dissolves it without acquiring colour, and sulphuric acid renders it brown.

Hyoscyamine exists in combination with an acid; it neutralises acids perfectly, and its power of saturation is great. The salts which it forms by direct combination with dilute acid mostly crystallise, are inodorous, but have an acrid nauseous taste, are unalterable in the air, and are extremely poisonous.

Hyoscyamine is a narcotic poison, like narcotine, and proves fatal as quickly as conine.

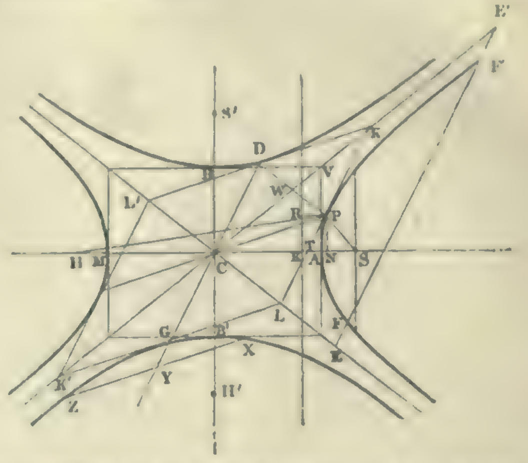
HYOSCYAMUS NIGER. The medical uses of *Hyoscyamus niger*, or henbane, have been detailed at the end of the article HYOSCYAMUS, in NAT. HIST. DIV.

HYPÆTHRAL. [TEMPLE.]

HYPE'RBOLA. In connection with this article see CONIC SECTIONS; ELLIPSE; PARABOLA.

The hyperbola is one of the curves known by the name of conic sections. It is in the application of mathematics the least useful of the three; indeed, so very rarely does the necessity of using it occur, that it may be a question whether the study of it should form a part of a course of practical mathematics. But there are in pure analysis so many analogies which are illustrated by distinctions existing between the properties of the ellipse and hyperbola, that the student who aspires to more than elementary knowledge cannot dispense with the comparison of the two curves.

The two branches passing through A and M form a complete hyperbola, derived from the cone, or from the general equation of the second degree. [CONIC SECTIONS.] There is a pair of straight lines passing through the CENTRE C, namely, L′C L and K′C K, which are ASYMPTOTES to the curve. There are two foci (as in the ellipse) S and H, the position of which may be thus found when the principal axis A M and the asymptotes are given: from A draw A V perpendicular to the axis; then C S and C H are both equal to C V.



The difference of the focal distances H P and S P is always equal to the axis major A M: in the branch passing through A, H P is greater than S P, and *vice versâ*. The tangent P T always bisects the angle S P H; and P N, the ordinate perpendicular to the axis, being drawn, C A is always a mean proportional between C T and C N. There is also a *directrix*, as in the ellipse, found by taking on the line C S, C E, a third proportional to C S and C A, and drawing through E a perpendicular to the axis; and, as in the ellipse, S P always bears the same proportion to P R, namely, that of C S to C A. And C S divided by C A is called the *excentricity*, the distinction between the ellipse and hyperbola being that in the former the excentricity is less than unity, and in the latter greater. The double ordinate drawn through S or H is called the *latus rectum* of the hyperbola, and its half the semi-latus rectum. Thus far the resemblance between the ELLIPSE and hyperbola is very visible: at the same time it is obvious that there is nothing in the latter which answers to the minor axis of the ellipse, or to conjugate semidiameters. But if another hyperbola be described in the manner immediately to be pointed out, a figure will be obtained which will enable us to point out properties answering in all respects to those of the ellipse. Complete the rectangle C A V B, and describe another hyperbola of which C B is the semi-axis, and the same lines as before the asymptotes. This hyperbola is said to be *conjugate* to the former one; and its foci S′ and H′ are at the same distance from the common centre as S and H.

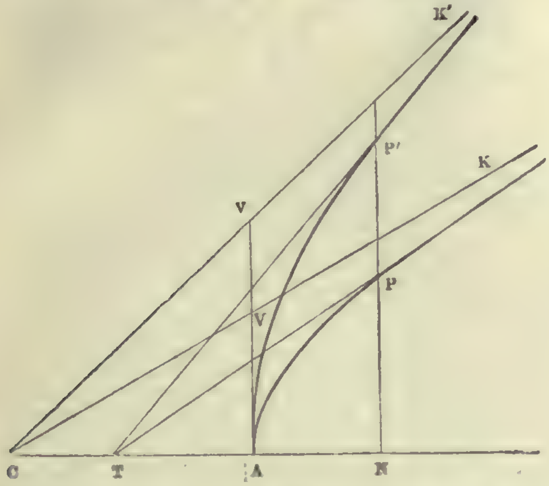
In the ellipse, C A was called the *major* semi-axis, as being greater than C B, the *minor* semi-axis. Let the words major and minor refer to the importance of the several axes, and not to their magnitude. Then C A is called the major semi-axis (or the semi-major axis) of the hyperbola passing through A and M, and C B its semi-minor axis. Conversely, C B is the semi-major axis of the hyperbola passing through B and B′, and C A is its semi-minor axis. Generally, the major axis of an hyperbola is that which cuts it, and the minor axis that which cuts the conjugate hyperbola.

As in the ellipse, the square on the ordinate P N is to the rectangle of M N and N A (which is the excess of the square of C N over that on C A) in the proportion of the square on C B to the square on C A. If C D be drawn parallel to the tangent P T, D is said to be conjugate to P, and the semi-diameter C D conjugate to the semi-diameter C P. . If the parallelogram P C D K be completed, the point K will always fall on the asymptote, and the other diagonal D P will be parallel to the other asymptote. And C P, any semidiameter falling in the acute angle of the asymptotes, always exceeds its semiconjugate C D; and the excess of the square on C P over that on C D is equal to the excess of the square on C A over that on C B. The area of the parallelogram C D K P always remains of one magnitude, namely, equal to C A V B. The rectangle of C W and W P always remains the same, namely, equal to the square on half the line joining A and B. Any part of a tangent K L, intercepted between the two asymptotes, is bisected by P, the point of contact; and if E E′ be drawn parallel to K L, the interceptions E F and E′ F′ are equal, and the rectangle of E F and F E′ is always equal to the square on P K or P L. And the rectangle of the focal distances H P and S P is always equal to the square of the semiconjugate diameter C P.

Any ordinate X Z drawn parallel to a tangent G L is bisected by the diameter C G drawn through the point of contact. And the square on Y X is to the rectangle of D Y and Y G (or the difference of the squares on C Y and C G) in the proportion of the square on C P to the square on C D.

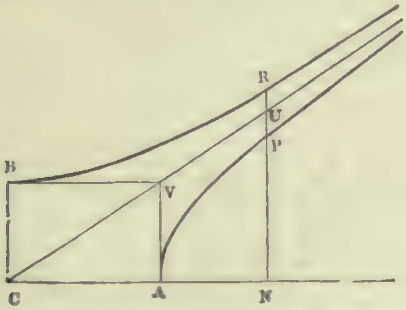
A perpendicular let fall from a focus S upon a tangent P T meets the tangent in a point of the circle whose centre is C and radius C A.

If any number of hyperbolas be drawn having the same centre C and the same major axis C A, and ordinates N P, N P′, &c., be drawn to the same abscissa C N, the tangents at P, P′, &c., will all meet the axis C A in the same point T: and any two such ordinates P N, P′ N, will



always be to one another in the proportion of the minor axes of the hyperbolas to which they belong.

If it were not necessary to consider the hyperbola in connexion with the ellipse, perhaps the following way of describing it would be the most simple.



Let C A be the semi-axis major, and C U one of the asymptotes: and while the line N U moves parallel to A V, let P move upon that line in such a way that the square on N P shall always be less than the square on N U by the square on A V. Then P will trace out one branch of the hyperbola. But if at the same time the square on R N *exceed* the square on N U by the square on A V, the point R will trace out a branch of the conjugate hyperbola.

For a remarkable property of the area of an hyperbola see LOGARITHMS.

Among ellipses there is one sort which is conspicuous, namely, the ellipse in which the major and minor axes are equal, or the *circle*. The corresponding hyperbola, namely, that in which the major and minor axes are equal, is called the *equilateral* hyperbola; and though not so remarkable a curve as the circle, yet presents some peculiar simplification of properties. Its asymptotes are at right angles to one another, and the hyperbola and its conjugate are similar and equal. Any semidiameter C P is equal to its semiconjugate C D, and P D is at right angles to C W. Its excentricity is $\sqrt{2}$ or 1·4142 ...., and the square on C N always exceeds the square on N P by the square on C A.

In the preceding article it will be observed that we have called the two branches passing through A and M *one* hyperbola. They are frequently called two *opposite* hyperbolas; but they form in fact only one curve, defined by one equation.

HYPERBOLE (*ὑπερβολή*, from *ὑπέρ* above, *βάλλειν* to throw) means literally an over-casting; in its common sense, a going beyond the truth in describing an object, not by the introduction of qualities which do not belong to it, but by the exaggeration of those which do. For example, it may be hyperbolical to say that the complexion of a fair woman is whiter than snow; but to say so of a brown woman is either irony or simple falsehood. Poets in all nations have affected this mode of speech; but it is peculiarly characteristic of the Oriental nations, both in prose and verse.

HYPERBOLOID. [SURFACES OF SECOND DEGREE.]

HYPERION, a Titan, the son of Uranus and Ge, and father of Selene, Eos, and Helios, who is often called Hyperion. [HELIOS.]

HYPERSPIROILIC ACID. [SALICYLIC ACID.]

HYPERTROPHY (from *ὑπέρ*, above, and *τροφή*, nutrition), a term in medicine signifying the enlargement of a part of the body from excessive nutrition. The hypertrophied organ contains no new solid or fluid substance, but one or more of its proper component tissues are in greater quantity than in the healthy state. The opposite condition of a part—namely, diminished bulk from defective nutrition—is termed atrophy. [ATROPHY.]

When hypertrophy attains such a degree as to interfere with the action of the organ in which it is seated, it constitutes an important and highly dangerous disease; such is frequently hypertrophy of the heart. [HEART, DISEASES OF.]

The immediate cause of the hypertrophied state is, as we have said, increased nutritive action in the organ or tissue; and since all parts of the body are formed and nourished from the blood circulating in them, it is natural to suppose that the production of hypertrophy would be accompanied by increase of the quantity of that nutritive fluid in the part. It is necessary, however, not merely that the blood should be collected in it in larger quantity, but also that it should circulate rapidly through the minute vessels, so as to bring constantly fresh portions of new nutritive matter into contact with the smallest component particles of the structure. This is illustrated by reference to the known exciting causes of hypertrophy which give rise primarily to this increased quantity and accelerated circulation of blood in the small blood-vessels. There are, it is true, instances of hypertrophy of which we cannot perceive any exciting cause: thus, in some persons the adipose tissue, or fat, in others the bones, are more than ordinarily developed, without our being able to assign any other reason for it than that there was a predisposition in the constitution of the individual to such increased nutrition. But generally we can refer the hypertrophy either to excessive exercise of the part, or to the long-continued action of a stimulus upon it. When any part is in a state of activity, a greater flow of blood takes place towards it than when it is at rest; and it is well known that a stimulus such as friction applied to a part of the body causes it to become of a brighter red colour from its vessels being more injected with blood. If such a state be long kept up, over-nourishment is the result. A popular example of hypertrophy from increased exercise is afforded by the muscles of the arms of the blacksmith, or those of the legs of the opera-dancer. The heart also frequently becomes hypertrophied from this cause; for instance, in cases where an increased action of its muscular walls is rendered necessary by an obstacle to the passage of the blood, which it propels into the body. Hypertrophy from the second cause, the long-continued operation of a stimulus, is seen in the thickened state of parts of the skin which have been subjected to friction. But hypertrophy from this cause is seldom simple; it is generally combined with the deposition of new matter of a different nature from the original tissue, the stimulus having excited inflammatory action as well as increased nutrition.

The treatment of hypertrophy consists in the removal of the exciting cause, if this can be effected: the part should be kept at rest as much as possible, all irritation prevented, and the supply of blood diminished. These means can, however, in very few cases be put into practice to such an extent as to be beneficial, except in arresting the progress of the affection.

(Andral, *Pathological Anatomy*; Carswell, *Illustrations of the Elementary Forms of Disease.*)

HYPERURIC ACID ($C_{10}N_4H_5O_9$), *Peruric Acid*, discovered by Unger, and formed by acting on guanin with hydrochloric acid and chlorate of potash. It differs in composition from uric acid by 1 equivalent of water and 2 of oxygen: hence its name. It is colourless, and crystallises in short rhombic prisms, and when heated is resolved into hydrated cyanic acid, water, and carbon.

HYPO and HYPER. [CHEMICAL NOMENCLATURE; *Nomenclature of Acids.*]

HYPOCAUSTUM. [BATH.]

HYPOCHLORIC ACID. [CHLORINE.]

HYPOCHLOROUS ACID. [CHLORINE.]

HYPOCHONDRIASIS, is a state of extreme sensibility of the nervous system, which leads patients to believe themselves worse than they really are, to detail their sufferings with exaggeration, to individualise all the painful sensations which they experience, and to consider them the symptoms of as many different diseases. Allied to this extreme sensibility there is a mental exaltation, which causes the patients to pay the most minute attention to what passes within themselves. The hypochondriac recounts, without a single omission, all the details of his animal and organic life; he relates the manner in which his digestion is effected; he numbers the minutes of his sleep; he describes his sensations, his passions, the succession of his ideas; and dilates on every thing that concerns himself with a copiousness that nothing can arrest. The story which he tells you to-day he will relate again to-morrow, and at all times whenever he can find you willing to listen to his tale of sufferings.

The case of a gentleman is related who was so engaged in attention to himself as to occupy the intervals of the visits of his physician in writing a journal of his sensations. This journal was, at every visit of the physician, produced for his perusal. During a period of several years this gentleman was, without any adequate reason, almost daily in dread of immediate death, and was continually upbraiding his medical attendant and charging him with the greatest cruelty in coming so seldom to see a man in such imminent danger.

As we do not in general see in hypochondriacs any loss of flesh or any appearances of disease corresponding to the frightful picture which they draw of their sufferings, we take them for visionaries; and such, in most instances, they really are. M. Leuret relates the case of a hypochondriac, who one day, among other symptoms of which he complained at great length, said that he could extend his leg slowly only and with difficulty, and to show to what an extremity he was reduced he lifted the limb with an appearance of great effort. "Well! what can you wish more?" inquired M. Leuret. "Zounds;" cried he abruptly, "to do this;" and at the same time he extended his leg with great freedom and force. M. Leuret could not restrain his laughter; and his patient, on perceiving the mistake that he had made, laughed also most heartily.

The sufferings of hypochondriacs have been called imaginary, and, if it is meant that they are a product of the imagination, the appellation is just; but the appellation of "imaginary" is false if it is pretended that they are not really felt. Of all patients, those whose diseases are imaginary probably suffer the most. In many cases however these persons are affected with a real disease, and the term hypochondriasis is applicable to them only in consequence of their having their attention constantly fixed on their complaint, and of their experiencing a degree of fear and sadness which their condition does not warrant.

Hypochondriasis is frequently witnessed in young men of studious habits, and is the result of intellectual application too much prolonged. There is a class of students who, from the nature of their studies, are frequently affected with it—we allude to students in medicine. The descriptions which they read and hear of diseases, and the continual observation of the sick, affect their imaginations. They learn that incurable diseases often arise in the most insidious manner. They apply to themselves the lessons they have just learned; but as these lessons are very incomplete, their application is false, and they discover in themselves a number of diseases of which there is no real existence. There are few physicians who, in recalling to their minds the period of their first studies, and the sick whom they first visited, do not at the same time remember the inquietude which they experienced respecting their own health. Persons in the habit of reading medical books run the same risk as medical students, and are similarly affected.

Another very fertile source of hypochondriasis is luxury, and the want of occupation and exercise. The hypochondriasis produced by this cause is the most obstinate of all, and is at once the despair of the patient and the torment of the physician. Happy are those whom the possession of a competence, earned by the labour of each day, preserves from such a malady. Poverty itself, with all its privations, is attended with less misery than the riches of the hypochondriac.

Hypochondriasis occasionally results from other causes, such as misfortunes, the excesses to which young men are addicted, and the prolonged and injudicious use of medicines.

The treatment of hypochondriasis must of course vary in some degree with its cause. We must endeavour to allay the groundless fears of hypochondriacs, and by a change in their mode of life, and by diverting their attention, to break the habit which they have formed of continually brooding over themselves. The first point, and which is quite essential, is that the patient should have an entire confidence in his physician. Confidence begets tranquillity, and banishes all those symptoms that originate in fear.

If hypochondriasis result from severe study, a relaxation from labour, and the distractions of society, with a country life, will prove the most efficacious remedies.

If it is occasioned by idleness and luxury, a solid and permanent cure can rarely be obtained except by a life of occupation, a moderate regimen, and bodily exercise long sustained. The field sports of this country are admirably adapted to the fulfilment of these conditions. Instances have been recorded of patients having been freed from the hypochondriasis to which they have been long a prey by the loss of their fortunes, or by some calamity which roused them from their state of apathy and rendered exertion imperative.

In all cases a remedy must be sought for in the banishment of their groundless fears, in a change in their mode of life, and in scenes that withdraw them from the continual contemplation of themselves.

HYPOGEIC ACID ($C_{32}H_{30}O_4$). An acid homologous with oleic acid, obtained along with *arachidic acid* by saponifying the oil expressed from the seeds of the *Arachis hypogæa*. It crystallises in needles, soluble in alcohol and ether. [Arachidic Acid.]

HYPONITRIC ACID. [Nitrogen.]

HYPONITROMECONIC ACID. [Opium, Alkaloids of; Narcotine.]

HYPONITROUS ACID. [Nitrogen.]

HYPOPHOSPHOROUS ACID. [Phosphorus.]

HYPOPION (from *ὑπώπιον*), a collection of purulent matter in the anterior chamber of the eye. Mr. Lawrence ('Treatise on Diseases of the Eyes') shows that this should not be regarded as a separate disease, but as the result of inflammation of some part adjacent to the anterior chamber. The purulent matter is in some cases secreted by the membrane of the aqueous humour; in others it proceeds from the bursting of an abscess of the cornea or of the iris. The pus poured into the anterior chamber being heavier than the fluid which naturally fills that cavity, falls to the bottom, and produces an opaque spot which is visible through the cornea, and has its upper edge horizontal, and its lower edge, which is bounded by the margin of the cornea, crescentic. The affection is always accompanied by inflammation of part or of the whole of the tissues of the eye, and, like all other such cases, requires active antiphlogistic treatment.

HYPOSULPHAMYLIC ACID ($C_{10}H_{12}S_2O_6$). An acid similar to the hyposulphethylic acid, but containing the radical amyl in the place of ethyl. [Hyposulphethylic Acid.]

HYPOSULPHETHYLIC ACID. Synonymous with *Ethylsulphurous acid.* [Ethyl.]

HYPOSULPHINDIGOTIC ACID. [Indigo.]

HYPOSULPHONAPHTHALIC ACID. [Naphthalic Group.]

HYPOSULPHONAPHTINIC ACID. [Naphthalic Group.]

HYPOSULPHURIC ACID. [Sulphur.]

HYPOSULPHUROUS ACID. [Sulphur.]

HYPOTHEC (from the Greek *ὑποθήκη*, a security, literally the subjection of a thing to the authority of another person) is a term derived from the civil law, still in use in the law of Scotland, and in that of France with the lingual variation *hypothèque;* while, though in the law of England it is not a received technical expression, it is occasionally used for describing any species of security holding the character which the word was employed by the civilians to represent. Hypotheca in its proper acceptation signified a right of security over something which was not placed in the creditor's possession, in contradistinction to pignus, which applied to what is now termed a pledge. See the distinction, pretty clearly drawn, in the Institutes of Justinian, 4. 6, 7 and in the Digest, 13. 7; 9. 2: "Propriè pignus dicimus, quod ad creditorem transit; hypothecam, cum non transit nec possessio ad creditorem." But the distinction is often lost sight of, even in the original authorities of the civil law; for the Roman lawyer Marcianus says that the difference between the two expressions is merely nominal (D. 20. 1, 5); and see Brissonius de Verborum Significatione, *voce* Hypotheca. Hypothecs were distinguished into those created by contract, and the tacit or prætorian, admitted in certain circumstances without stipulation. The law on the subject will be found in the Pandects, lib. xiii. tit. vii. de Pignoratitia Actione, &c. (above referred to); in lib. xx. de Pignoribus et Hypothecis; and in the Code, lib. viii. tit. xiv. The reader will also find a short but clear summary of the Roman rules on this subject in Warnkœnig's 'Institutiones Juris Romani,' lib. ii. cap. v. §§ 450–478.

The several securities over real property in various parts of the empire, which can be completed without the absolute transfer of the property to the creditor, are so many illustrations of consensual hypothecs in that description of property. Consensual hypothecs in moveables are nearly unknown in the British empire, as the law, studying the interests of commerce, has discouraged any latent right in favour of an individual over merchandise and other moveable goods while they are left apparently at the disposal of the original owner, and are liable to be viewed by all who transact with him as his property. Bottomry and Respondentia are perhaps the only instances in which it is countenanced. But there are still some tacit hypothecs created by the operation of law, affording a preference to particular creditors over the property of a person who cannot or will not pay all his debts. Used in this sense, hypothec is properly the counterpart of lien, the former being a tacit security over property which is in the debtor's hands, the latter over property in the creditor's hands. Those provisions in the excise laws which give the revenue a preference over exciseable commodities, and the instruments used in their manufacture, are strictly the creation of tacit hypothecs. The provisions in the bankrupt acts for paying servants' wages and other debts out of the readiest funds of the bankrupt are the establishment of a general hypothec over the estate.

In Scotland, the landlord's privilege to seize the tenant's goods for arrears of rent is called a hypothec while it is unexercised; that is to say, before execution against them is commenced the landlord is said to have a hypothec over the goods; and this right, it is said, covers not only the ordinary rent, but also the additional rent stipulated in the event of deviation from the terms of the cultivation clauses (but this doctrine has been strongly attacked). On an agricultural farm the crop stands hypothecated for the rent of the year of which it is the produce. The landlord's right exists so long as the crop is on the farm, and it extends to the revendication of it even from a *bonâ fide* purchaser within three months after the rent has fallen due, unless he have been a purchaser by bulk in open market. The hypothec for other effects—as the cattle on a farm, the tenant's furniture in a house—subsists over the whole for each term's rent, and gives a preference for three months after the rent is due. The landlord's hypothec is not affected by the bankrupt statutes. In Mr. Hunter's able treatise on 'Landlord and Tenant,' the origin and effect of this branch of the law of Scotland is discussed with great clearness and precision, and for the purposes of practical reference the reader is referred to that work; the following points, however, extracted from it, are deserving notice: 1st, that the earliest, and indeed the original, remedy given the landlord for the recovery of his rent, was by brieve of distress; and that, 2ndly, it was not till the beginning of the 17th century (1623) that the term hypothec appeared in the decisions, from and after which period distress ceased and hypothecation prevailed; 3rdly, that there is so obvious a distinction between these two remedies, arising from the more extensive operation of hypothecation in following and realising the effects, as to lead to the conclusion that the rules and phraseology of this system are drawn directly from the Roman jurisprudence; 4thly, that the Scotch right of hypothec is not to be deemed a right of property, but a right arising from a tacit contract, inseparable from the contract of lease; 5thly, that this right is purely legal, and cannot be created by convention,—the only conventional hypothecs known to the law of Scotland being bottomry and respondentia; and, lastly, that the rules relative to hypothec have arisen from the common law without the intervention of statute. Another right of a different description is called a hypothec in Scotland—namely, the right of a law agent to take his client's decree for expenses, or judgment for costs, in his own name, in order that he may recover payment of his account as taxed by the auditor of court. This right cannot be defeated by a collusive settlement. In Scotland, a law agent, whether employed to conduct a litigation or in other professional business, such as conveyancing, is entitled to retain his employer's title-deeds and papers until his just account is paid. This right has also been called a hypothec; but it is clearly a lien. For further information on this part of the Scotch law of hypothec, the reader is referred to Bell's 'Commentaries,' vol. i.

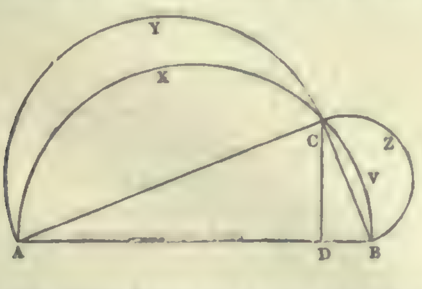
In France there is a distinction between privilèges and hypothèques. All tacit hypothecs, according to the division above kept in view, are included under the former, which are subdivided into a general preference over all the moveables or personal property in the debtor's possession, and limited preferences over particular articles of property for particular obligations. This last named, in so far as it affects moveable property, is the class of rights which has been spoken of above as tacit hypothec, and it includes the landlord's security for his rent. There is also a classification of privilèges sur les immeubles, consisting of tacit preferences over what is in England called real property, and of privileges which extend to both moveable and immoveable property. The term hypothèque is applied to conventional securities over immoveable or landed property, and is the object of much useful legislation; such securities being, from the efforts to give virtual effect to the law for partition of successions, without reducing them below the proper extent for agricultural operations, more common in France than perhaps in any other part of the world. See on the matter of the immediately preceding remarks, 'Code Civil,' lib. iii., tit. 18; and Troplong, Droit Civil expliqué, 'Privilèges et Hypothèques.'

HYPOTHECATION. [Mortgage.]

HYPOTHENUSE or HYPOTENUSE (ὑπο-τεινουσα, subtending), is a term which has always been applied since the time of Euclid to the side of a *right-angled* triangle which subtends, or is opposite to, the right angle.

The property of the hypothenuse of a right-angled triangle being one of the most important elementary propositions in the whole of mathematics, it will be worth while to devote some space to its consideration. We shall proceed to give some demonstrations, derived from different principles.

The property in question, in a limited form, is this: that the *square* on the hypothenuse is equal to the sum of the *squares* on the sides. The introduction of the square, however, in preference to any other figure, arises from the fact of the property of the hypothenuse with respect to the square being demonstrated before that with respect to any other figure. The general proposition is this: if three similar figures (that is, figures of the same shape, differing only in size) be described upon the three sides of a right-angled triangle, the content of that which is described upon the hypothenuse will be equal to the sum of the contents of the figures described upon the sides. Thus, all semicircles being similar figures, let A X C B, A Y C, and C Z B, be the semicircles described on the hypothenuse and sides of the triangle A C B, right angled at C: then A Y C and C Z B are together equal to A X C B. Hence was obtained the first instance in which a curvilinear space was reduced to an equivalent rectilinear one. Take away the segments A X C and C V B from both sides of the preceding equation, and the remainders of the smaller semicircles, namely, the *lunules* Y X and Z V, are together equal to the remainder of the larger one, namely, the triangle A C B. This proposition is attributed to Hippocrates. [Geometry.]

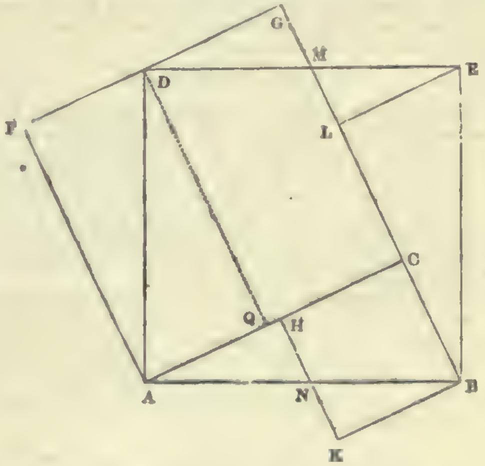


So soon, however, as the proposition is demonstrated with respect to squares, all the rest follows easily, after the doctrine of proportion has been established. It is the property of similar figures described on two lines to be in the same proportion as the squares on those lines; if then the squares on two lines be together equal to that on a third, then any two similar figures described on the first two lines are together equal to the corresponding figure described on the third.

We shall now sketch four different demonstrations of this fundamental proposition, desiring it to be remembered that we suppose the reader to have already become acquainted with it in an elementary course of geometry.

1. Let C D (in the preceding figure) be drawn perpendicular to A B. Suppose that (after the manner of some writers on geometry) the theory of proportion and of similar triangles is established before anything is proved relatively to the areas of figures. Then it is easily shown that A C D and C D B are triangles similar to one another, and to the whole A C B. Now in such a system of geometry, it can easily be shown, without the aid of our theorem, that any two similar figures, described on two straight lines, are to one another in the proportion of the squares on those lines. Consequently, A C B, A D C, B D C, being similar triangles described on A B, A C, B C, are to one another as the squares on A B, A C, B C. But the first triangle is evidently equal to the sum of the other two: consequently, the square on A B is equal to the sum of the squares on A C and C B. This demonstration may be objectionable in a geometrical point of view, but it contains one of the most useful modes of illustrating the proposition to a person unacquainted with geometry. Let such a one be made to remark the very visible fact, that two similar figures described on two straight lines are always of the same relative magnitude, each to the square described on the same line: he will then, seeing that the right-angled triangle is made up of two right-angled triangles similar to itself, each having one of the sides for its hypothenuse, be able to see that the square on the hypothenuse is equal to the sum of the squares on the sides.

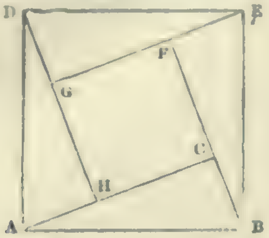
2. The next method shall be ocular demonstration, made by cutting the square on the hypothenuse into the squares on the sides. Let A C B be the triangle, right-angled at C; and on A B describe the square A D E B, and on A C and C B the squares A F G C and C H K B. From E draw E L perpendicular to B M, and from D draw D Q perpendicular to A C. It is easily proved that the triangles A C B, B L E, D Q A, are equal in all respects; whence (1) the line F G must pass through D, since D Q = A C; (2) E L = B C = B K. Hence, by the parallels, the triangles N K B and M E L are altogether equal, so that E M = B N, whence M D = N A, and, by the parallels, D G M and A H N are altogether equal. And A F D is in all respects equal to B L E. Out of the square A D E B take B L E, and remove it to A F D; remove M L E to N K B, and A H N to D G M. Then the square A D E B will be formed into the two squares A F G C and H C B K.



In a paper by Professor Kelland, 'On Superposition' ('Edinb. Trans.' vol. xxi. p. 2) are *twelve* different ways of dissecting a square into two squares, one of which shall be three times the other. This paper suggested to Mr. Airy, the Astronomer Royal, the following very simple mode of making *any* two squares into one; from which a demonstration of i. 47, may be derived of a more elementary character than that given by Euclid himself. Place the squares A G, K C, side by side, as in the preceding diagram; and make G L equal to B C, as before. Join F, L and L, K, then F L, L K are equal and perpendicular to each other. Turn the triangles F G L, L B K, round the points F, K until F G coincides with F A, and K B with K H. The two squares will thus be turned into the square on F L or L K. The same thing may be done by translation of the triangles, without rotation. It is rather singular that, many as have been the eyes which have rested on the preceding diagram, no one should ever have made it yield the dissection just given.

Each mode of demonstrating a geometrical proposition usually belongs to its own particular generalisation of that proposition. The one last before us suggests the following generalisation:—If any two triangles have a pair of supplemental angles, and if the sides opposite to those angles be called hypothenuses, and if P, Q, be the remaining sides of one triangle, and P′, Q′, of the other, then two parallelograms having the supplemental angles for their angles, and P and P′ for the sides of one, and Q and Q′ for the sides of the other, are together equal to the parallelogram under the hypothenuses inclined at one angle equal to the sum of those opposite to P and Q′, or to P′ and Q.

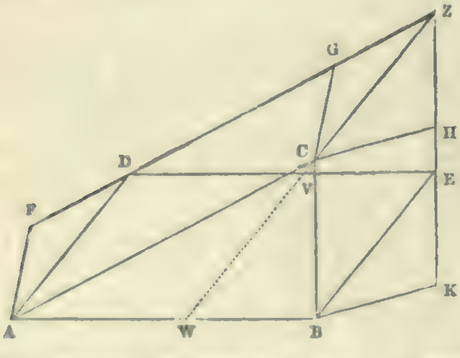
3. The next demonstration is derived from the Hindu treatises on algebra: not that it is actually found there, for the Hindu works demonstrate nothing; but attached to the statement of the proposition, in the margin of some copies, is the following diagram, which is no doubt that belonging to the demonstration, which is as follows:—Let ACB be the triangle, and describe the square ABDE on the hypothenuse. Draw DH perpendicular to AC, and EG perpendicular to DH, and produce BC to meet EG in F. Then the square is made up of the four equal triangles ACB, BFE, EGD, DHA, and of the smaller square GFCH, which is the square on HC, the difference of AC and CB. But the four triangles make up twice the rectangle of AC and CB, and twice the rectangle on two lines, together with the square on their difference, is the sum of their squares: whence the square on AB is the sum of the squares on AC and CB. Judging by the general character of Hindu mathematics, it must be supposed that their demonstration was arithmetical, supposing the sides of the triangle to be represented by numbers, and using the equation



$$(a-b)^2 + 2\,ab = a^2 + b^2.$$

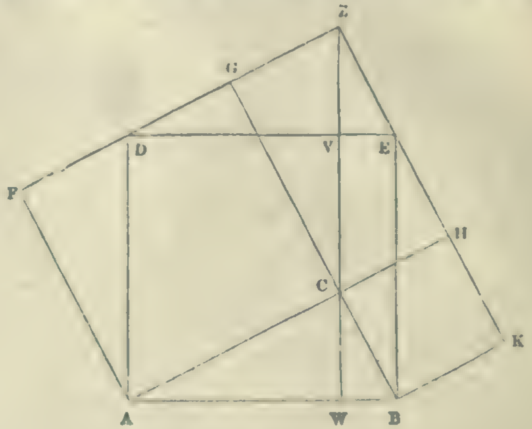
The following is the method of obtaining right-angled triangles, of which the sides shall be whole numbers. Take any two whole numbers whatsoever, x and y, of which x is the greater; then if x^2-y^2 and $2\,xy$ be the two sides of a right-angled triangle, the hypothenuse is x^2+y^2. For instance, let $x=11$, $y=7$; then $x^2-y^2=72$, $2\,xy=154$, and $x^2+y^2=170$: whence 72 and 154 being sides of a right-angled triangle, its hypothenuse is 170. It is a remarkable property of any three numbers which represent the sides of a right-angled triangle, that one of them must be divisible by 5.

4. The last demonstration which we shall give is one which shows the property in question to be but one simple and prominent case of a property of great beauty and generality, common to all triangles. This property was first noted by Pappus, and it shows that any parallelograms whatsoever being described upon the two sides of a triangle, a third parallelogram, equal to their sum, can immediately be drawn upon the third side.



Let ABC be a triangle, on two sides of which, AC and CB, let any parallelograms AFGC and BCHK be described. Produce FG and KH to meet in Z, and join ZC, and produce it to W. Through A and B draw AD and BE parallel to ZW, whence it follows that ADZC and CZEB are parallelograms, and, by equality of bases and altitudes, severally equal to AFGC and CHKB. And AD and EB are equal and parallel to ZC, and therefore to one another; whence ADEB is a parallelogram made up of the parallelograms ADVW and BWVE, which, by equality of bases and altitudes, are severally equal to ADZC and BCZE, that is, to AFGC and CHKB. Hence the parallelogram on the side AB is equal to the sum of those on the sides AC and CB.

Now let the triangle be right-angled at C, and let the parallelograms on AC and CB be squares, and repeat the preceding construction. Then GCHZ is a rectangle, and GZC is in all respects equal to ACB, whence ZC=AB, and thence AD and BE are equal to AB, and the parallelogram DEAB is equilateral. But the angle DAC is equal to ZCH, which is equal to CBA, the triangles CZH and BAC being altogether equal. But CBA and CAB are together equal to a right angle; whence DAC and CAB are the same, or DAB is a right angle. Consequently, ADEB is an equilateral parallelogram, right angled at A, or it is a square; and the parallelogram ADEB, that is, the squar on AB, is equal to the sum of the parallelograms AFGC and CHKB, that is, to the sum of the squares on AC and CB.



HYPOTHESIS (*ὑπό-θεσις*, *sub-positio*, supposition), literally, the act of placing one thing under another, that the latter may stand upon and be supported by the former; by extension, the assignment of cause or reason sufficient to make it a consequence that an event or phenomenon must happen. For instance, the sun would disappear if it were deprived of its power of giving light, and also if an opaque body came between us and it: either of these circumstances would cause what we term a total eclipse, and either is therefore sufficient, as an hypothesis, to explain a total eclipse.

In the article CAUSE (in natural philosophy) will be found the discussion of several considerations connected with the use of hypotheses; and in the article ATTRACTION an instance of the important distinction between an hypothesis asserted because it is true, and one assumed because it is sufficient to explain observed phenomena. We suppose these articles to be known to the reader.

The following mode of argument is known in logic by the name of a hypothetical syllogism:—If A exist, Z exists; but A does exist, therefore Z does exist. Or, establish the absolute truth of an hypothesis, and the phenomena which necessarily follow may be asserted even without experiment. But this we are seldom in a condition to do. The preceding process cannot be converted: if A exist, let Z necessarily follow; Z has appeared, are we then entitled to say that A exists? By no means; for when we prove that Z necessarily follows from A, we do not therefore show that Z follows from nothing but A. But if we can establish the following:—If A exist, Z follows; if B exist, Z follows; if C exist, Z follows; and Z cannot happen in any other way: then from the arrival of Z we are entitled to assume that one of the three, A, B, or C, must necessarily exist, perhaps two, and perhaps all three. At the same time, if the existence of the consequence can be denied, the hypothesis is overthrown. If A exist, Z follows; but Z does not happen; then it is perfectly certain that A does not exist. The following summary of the four cases may be more worthy of our readers' consideration than many of them will suspect:—

1. When A is B, Y is Z.
   But A is B. } Therefore Y is Z.
2. When A is B, Y is Z.
   But A is not B. } Nothing can be concluded: Y may be Z on some other grounds, or Y may not be Z precisely because A is not B, or for some other reason.
3. When A is B, Y is Z.
   But Y is not Z. } Therefore A is not B.
4. When A is B, Y is Z.
   But Y is Z. } Nothing can be concluded: A may be B, and either because Y is Z, or for some other reason; and A may not be B, and there may be some other reason why Y should be Z.

The establishment of an hypothesis in natural philosophy may be considered as a process of which the following are the heads:—

1. The phenomenon observed is Z, and it is shown to be a necessary consequence either of A, B, or C, which seem natural and probable: also of D, E, &c., which seem altogether out of the question.

2. All the necessary consequences which can be shown to follow A, B, or C, are deduced as far as that can be done; and if all their consequences really happen, then there is no choice between A, B, and C; but if Z′, a necessary consequence, say of C, should be found not to happen, then C cannot exist, and the choice can only lie between A and B.

3. Let A appear the more probable of the two, then A is assumed to be the cause of Z until something to the contrary appears. If A and B should be inconsistent with one another, then if one be assumed, it

must be to the exclusion of the other; but if both may be true, then the phenomenon E may possibly be partly due to one and partly to the other.

An hypothesis thus assumed is obviously no more than a probable truth; and the existence of sects embracing different hypotheses is thus rendered not only natural, but even desirable. The consequence of such division is, an ardour of investigation which would not otherwise be felt, in order to find out experiments or to make deductions decisive of the points in dispute. The rivalry between the emanatory and undulatory hypotheses on the nature of light has much increased our knowledge of that agent. But if at the same time it should seem that the idea which a reader entertains of physical science must be lowered by his learning to take such a view of a hypothetical foundation as that which has here been given, it should also be remembered that the exactness of natural philosophy does nothing but expose the uncertainty of human knowledge in general, at the same time that it reads a lesson to the cultivators of other branches of learning. The hypothesis of attraction, for instance, though established on much stronger grounds of probability than conclusions in connexion with which the word hypothesis is never mentioned, is remembered as being only an hypothesis.

At the same time the word hypothesis, like that of theory, has been frequently applied in a disparaging sense to speculations in which suppositions have been made for the purpose of drawing conclusions, and not, as in physics, with the view of supplying probable antecedents to conclusions which are already drawn from experiment. A notion is to be supported; it would be too obvious a fallacy to make the mere assertion of it an argument in its own favour, and thus some antecedent proposition, from which the one in question will follow, is assumed or attempted to be proved. To prove D, assume A, taking care that it shall be easy to show that from A follows B, from B follows C, and from C follows D. This is a use of hypothesis the direct converse of that which is made in physics, where D is supposed to be known and admitted, and it is asked which among all the A's from which it might follow is that from which it most probably does follow. [CAUSE.]

HYPOXANTHIN ($C_{10}H_4N_4O_2$). A peculiar substance met with in the fluid of the human spleen, and also in that of the ox. It has also been found in the fluid pressed from the muscles of the heart, and in small quantity in the blood of oxen. It presents the appearance of a white crystalline powder, which is almost insoluble in cold hydrochloric acid. One part of hypoxanthin requires 1090 parts of cold, or 180 parts of boiling, water for its solution. It is very slightly soluble in boiling alcohol. Its solution in water possesses a neutral reaction.

HYPSOMETRY. The process by which heights are measured by the indications of the barometer. [HEIGHTS, MEASUREMENT OF; BAROMETER.]

HYSTERIA (from *ὑστέρα*, the womb) is, in general language, understood to signify those paroxysms to which females are subject, and which are attended with convulsions, a sense of choking, and involuntary laughing or crying. But the term is used in medicine as a general expression to include a vast number of other symptoms known as "nervous disorders," all dependent on a peculiarly susceptible state of the nervous system.

We will first consider the different forms of hysteric affection.

The hysteric fit or paroxysm need scarcely be described, except for the purpose of pointing out how it may be distinguished from fits of other kinds; and this is a matter of no little importance, not only as regards the treatment required and the temporary alarm of the friends, but also with relation to the happiness and prospects of the sufferer. For it appears that in France, at least, young females labouring under mere hysteria have been separated from their families and society, and placed in confinement under the idea that they were the subjects of epilepsy, a disease which is thought to be hereditary, is but too often incurable, and leads to loss of intellect. The hysteric paroxysm generally commences with the sensation of a ball in some part of the abdomen or in the left side, which rises with a twisting vermicular feeling to the throat, where it induces a sense of suffocation. A temporary state of loss of sense and voluntary power succeeds, in which the patient either lies motionless, or is agitated with violent struggles of the limbs; the head is struck against the bed or floor, and the hair or the breasts are grasped and torn with the hands. Frequently the patient tries to bite herself or the bystanders. The involuntary expulsion of the contents of the bladder not uncommonly takes place during the fit. In the absence of convulsions there is often immoderate laughter, crying, or singing, and the paroxysm is frequently terminated suddenly by a burst of tears. More usually the patient lies quietly for some time after the convulsions cease, and when she recovers complains of headache. Frequently she proves that consciousness has not been entirely lost, by repeating what has been said by those around her. The attack of epilepsy differs from that of hysteria in not being preceded by any sensation of a ball rising to the throat; the epileptic patient falls suddenly to the ground, and is immediately violently convulsed; the eyes are distorted, and the tongue protruded and bitten. In hysteria the features are generally tranquil, and the face is flushed; whereas in epilepsy it is often of a ghastly paleness. The epileptic fit is in many cases ushered in by a short cry, but there is no laughing, crying, or singing during the paroxysm, or at its termination, as in hysteria. Lastly, the loss of consciousness is complete in epilepsy, generally not so in hysteria. These are the principal points of difference. It is well to remark in addition that hysteria is almost confined to women, and that the paroxysm is generally preceded by some strong mental emotion; while epilepsy is most frequent in men, and more usually attacks the patient during the night, or between the states of sleep and waking. Repeated attacks of epilepsy leave imprinted on the countenance a peculiar dull expression which is not seen in the hysterical.

"Nervous" females are very liable from the slightest causes to hurried respiration, sighing, sobbing, and palpitation; the irregular and hurried breathing may become occasionally so aggravated as to resemble asthma, from which it is to be distinguished by its occurring in young persons, and by its being accompanied by other hysterical symptoms, and a peculiarly irritable susceptible state of mind.

Merely from a disturbed action of the nerves, and quite independently of all real structural or inflammatory disease, females frequently become distressed by more or less painful sensations fixed in one spot or shifting from one part to another. Violent pain in the head, as if a nail were driven into the forehead, is a very common hysterical symptom. Another frequent seat of the uneasiness or pain is the left side, just below the breast, and this pain is often attended with palpitation of the heart, and the patient is unable to lie on that side. Sometimes excruciating pain occupies the whole abdomen. In all such cases it will be found that the disease, simulated by the hysterical affection (whether it be of the head, chest, or abdomen, or of one of the large joints), cannot exist, since other symptoms essential to constitute it are absent. The pain of hysteria too, besides being frequently transitory and unfixed in its seat, has generally the peculiarity of being aggravated by the slightest touch of the skin, which is not the case with pain arising from inflammation. With this external tenderness there is frequently great tenderness along the course of the spine, and this is frequently greater at one particular spot.

Other symptoms of a decidedly hysterical or nervous nature will perhaps be present, or a true hysterical paroxysm may supervene. It is important to know that symptoms of almost every disease may be simulated by hysteria, which, though a troublesome affection for the sufferer, is unattended with danger. It is when real disease is present, and complicated with nervous or hysterical symptoms, that it requires the greatest acuteness of the physician to discern what proportion of the symptoms is of the latter kind, and what due to the more important affection.

Hysteria sometimes assumes the form of different paralytic affections the power of moving the arm, or the voice, may be lost. These phenomena may be of considerable duration, but are ultimately, and often suddenly, recovered from. The state of long-continued stupor which has received the name of "trance" is most commonly hysterical. Different spasmodic affections, as hiccough and spasm of the throat, preventing swallowing, not unfrequently occur in the hysterical state. Then, again, certain disordered states of the senses and mental faculties and feelings occur, as the consequence of uterine or sexual irritation, and are to be referred to hysteria. Such are somnambulism, some kinds of transitory monomania, and those peculiar perversions of the mind manifested in the desire to feign various diseases. The occasional occurrence of hysterical paroxysms, the irritable state of mind, the knowledge that the mind has been acted on in a way calculated to excite the affections, and the presence of other phenomena decidedly hysterical, will assist in detecting the true nature of all these cases.

There is certainly a peculiar state of the system which predisposes to the affections which we have thus cursorily described, for the causes by which they are excited have nothing peculiar in themselves. All the phenomena indicate a disordered state of the nervous system, and the exciting causes are such as act either through the medium of the body or the mind on that system. The susceptible state of the nervous system, which predisposes it when thus acted on to give rise to the various hysteric phenomena, is without doubt frequently connected with or kept up by an excited condition of the uterine system and the sexual feelings; with no system of organs and no feelings of the mind does the nervous system of females so much sympathise. This conclusion is confirmed by the fact of hysteria occurring in a great proportion of cases between the age of puberty and that at which the catamenia cease, during which period the uterus is in a state of greater activity than before and after it; and by the circumstance of its being at the commencement and termination of that period, when the uterine organs are undergoing the greatest changes, and the feelings of the mind connected with them are most disturbed, that the attacks of hysteria are most frequent and violent. It is from their supposed connection with particular states of the uterus that the attacks have derived their name. Other facts, however, show that a predisposed state of nervous system is necessary, for vascular excitement and structural disease of the uterus may exist without giving rise to hysteria; and that other functions, as those of the digestive organs, being disordered, may act on a susceptible person so as to aggravate the tendency to hysterical symptoms, or even excite them. In some females, having the requisite nervous susceptibility, a mere plethoric state of the body, without any affection of any special organ, will excite hysteria; the opposite state, deficiency of blood in the body, will have the same effect: anything, in fact, which throws the system of such irritable females out of the natural state, whether it act primarily on the body or mind, may give rise to nervous symptoms or hysteria. From the frequent occurrence of a deranged state of the blood and secretions, some forms of this disease have been called *anæmica*.

The most frequent exciting cause of the hysterical paroxysm is, perhaps, a sudden and intense emotion of the mind.

Treatment.—During a fit of hysteria, care should be taken to prevent the patient receiving injury from her head or hands striking against the floor or hard bodies, and to guard against the propensity to bite, by placing a folded cloth between the teeth. If the fit be slight, it may frequently be arrested by dashing cold water over the face, or by filling the mouth with something which has an unpleasant taste, as salt; or a stimulating scent may be held to the nostrils. If the paroxysm be more prolonged and violent, it will be proper, should the face be flushed and head hot, to apply wet cloths to the forehead, and to loosen all the dress about the neck and chest. If a continued stupor intervene, medical aid may be required. When there is less fulness about the head, small doses of stimulants, such as sal volatile in water, will be useful.

When the frequent return of the fits seems to depend on a full state of body, or on irritation, means calculated to remove these causes must be adopted. If an unnatural state of the uterine functions be suspected, these must be attended to. Frequently the sufferer from hysteria is feeble and bloodless, and in a state of general nervous debility; in such persons, all measures likely to strengthen the general health, proper diet, regular hours, change of air, and tonic medicines, should be put into practice. The preparations of iron are especially useful. The state of mind of the patient should, in these cases, be particularly regarded.

For the treatment of the pains and other anomalous nervous symptoms no rules can be laid down; they will frequently resist all modes of palliative treatment. The great principle, however, must not be forgotten of removing all causes which can re-act prejudicially on the nervous system or the general health.

The nervous susceptibility which predisposes to hysteria is, without doubt, frequently innate or constitutional; but it is certainly in many cases acquired; and it is often to be attributed, in a great measure, to the education of young females. "A luxurious and delicate mode of living and of rearing," says Dr. Copland; "a neglect of whatever promotes the powers of the constitution, especially of suitable exercise in the open air, and of early hours as to sleeping and rising; an over-refined mode of education, and the excitement of the imagination and of the emotions, to the neglect of the intellectual powers and moral sentiments; too great devotion to music, and the perusal of exciting novels; the various means by which the feelings are awakened and acute sensibility is promoted, whilst every manifestation of either is carefully concealed; and studied endeavours to dissemble desires which struggle to be expressed,—all serve, especially at a period when the powers of the mind and the conformation of the body are approaching development, to produce that state of the nervous system of which hysteria is one of the most frequent indications." The prevention of hysteria cannot certainly be hoped for until the education of females is directed more towards strengthening their body and improving the tone of their mind, so as to enable them to bear disappointments, and to control, not merely conceal, their passions.

I

I is a vowel which represents two very different sounds in different languages. In this country it denotes a rapid pronunciation of the diphthong *ai*. In French, Italian, and many other tongues, its sound is identical with that of the English *e*. In the series of the vowels established by the experiments of Mr. Willis [ALPHABET], *i*, as denoting the latter sound, lies at one of the two extremes. It is pronounced with the lips retracted so as to shorten the vocal tube, whereas the same organs are protruded to produce the sound represented at the other extremity by *u*. The various forms which have been used to represent the letter *i* may be seen in the article already quoted, cols. 240, 241. The character there given as used by the Phœnicians and early Greeks is somewhat complicated, and differs widely from the single stroke into which it eventually degenerated. In this last state it was the simplest of all the alphabetical characters, and was therefore well adapted to be the symbol of a small quantity. In this sense the terms a *jod* and an *iota* are still retained, *jod* being the Hebrew, *iota* the Greek name for the character.

The letter is interchangeable as follows:—

1. With the diphthongs *ai, oi, ei*. This may be seen most distinctly in the Latin language, where *alais, requairo, pueroi, puerois, nulloius, deico*, &c., were corrupted into *ālis, requīro, puerī, puerīs, nullīus, dīco*. In the same language, when one *i* was followed by another *i*, it was not uncommon to denote them by a single long *i*, as *tibīcen, Chīus, alīus* (gen.), *inscītia*, for *tibiicen, Chiius, aliius, insciitia*. In such cases it was a common practise to give greater length to the letter, thus, CHIVS.

2. The short *i* was interchangeable with nearly all the short vowels, more particularly in the penult syllables of polysyllabic words, which are very indistinctly pronounced. Thus the Greek *mēchănē* is in Latin *māchĭna*. In the same manner the Nomad races of North Africa are called by the Greeks *Nomades*, by the Romans *Numidae*. Again, ἄνεμος and *animus* are kindred words *Bonitas* must have been originally *bonotas*, and would have been written in Greek with a termination -οτης. Lastly, in a large number of words a short *u* degenerated into an *i*: as *maxŭmus, decŭmus, recŭpero, maritŭmus, scribŭmus* (compare *sŭmus*), into *maximus, decimus, recipero, maritimus, scribimus*. Even Cicero wrote all these words with a *u*, though our editions give an *i*.

3. A short *i* before *n* or *m* is not unfrequently in French changed into *ai* or *a*. Thus the Gallic town *Inculisma* is the origin of the name *Angoulême*: *vincere* is in French *vaincre*, &c.

4. In the same language the vowel *i* is changed into *oi* very commonly, as *sitis, soif; mi, moi; fides, foi; Ligeris, Loire*, &c., and this though the *i* in Latin be short.

5. *I* is often inserted in French or Spanish words before the vowel *e*: *miel, bien, vient*, &c., from the Latin *mel, bene, venit*.

6. The vowel *i* is often inserted after the vowels *a, o*, and *u* in the French language, particularly when a contraction has taken place, as *aimer, connoître, reduire*, from *amare, cognoscere, reducere*.

7. When the vowel *i* in the Latin language has a vowel after it, and is preceded by one of the consonants *p, b; t, d; c, g;* the derived languages have often a sibilant in the place of the former consonant. Thus *sapiam* is in French *sache*: *rabies, rage; ratio, raison; medius*, in Italian *mezzo* (compare the Greek μεσος). The double sound of *c* and *g* in our own language appears to have originated in this way.

8. A similar change occurs even in other cases, as *simia*, Fr. *singe*; *vindemia, vendange; lineus, linge*.

IAMBICS, a species of verse composed of a succession of iambi (˘ ¯), or equivalent feet, was freely used both by Greek and Latin poets. According to Aristotle ('De Poetic.'), the iambic measure was first employed in satirical poems, called *iambi*, which appear to have been represented or acted; since Plato ('De Rep.,' vii. 17) forbids boys to be spectators of iambi and comedies. The iambic is the most common metre in the Greek tragic poets. We are informed by Aristotle ('De Poetic.') that "originally the trochaic tetrameter was made use of, as better suited to the satyric and saltatorial genius of the poem at that time; but when the dialogue was formed, nature itself pointed out the proper metre; for the iambic is of all metres the most colloquial, as appears evidently from this fact, that our common conversation frequently falls into iambic verse, seldom into hexameter, and only when we depart from the usual melody of speech." (Twining's 'Transl.,' part i., c. 4.)

In the following table a list is given of the feet which may be admitted in the iambic metre in the Greek tragic poets, which is usually called the tragic trimeter acatalectic, because it consists of three entire metres, or six feet:—

1	2	3	4	5	6
˘ ¯	˘ ¯	˘ ¯	˘ ¯	˘ ¯	˘ ¯
˘ ˘ ˘	˘ ˘ ˘	˘ ˘ ˘	˘ ˘ ˘	˘ ˘ ˘	
¯ ¯		¯ ¯		¯ ¯	
¯ ˘ ˘		¯ ˘ ˘			
˘ ˘ ¯					

The anapæst in proper names is also introduced in every place of the verse except the last, with this general restriction,—that the anapæst should be contained in one word. The comic trimeter admits the same feet as the tragic, and also a dactyl in the fifth place, and an anapæst in common words in every place but the last.

Much of the beauty of the iambic trimeter depends upon the cæsura [CÆSURA], which usually occurs in the middle of the third or the middle of the fourth foot; as, for example:—

> *οἱ μὲν θέλοντες | εκβαλεῖν ἕδρας Κρόνον.*
> *ἱκτηρίοις κλάδοισιν | ἐξεστεμμένοι.*

One of these cæsuras may be considered as generally necessary; the cæsura in the middle of the third foot is much more common than in the middle of the fourth. There is also frequently a cæsura in the middle of the second or the middle of the fifth foot. When a line is divided in the middle of a verse with the elision of a short vowel, or of the little words δὲ, μὲ, σὲ, γὲ, τὲ, that division is called by prosodians the *quasi-cæsura*; as, for example:—

> *γυναιξὶ παρθένοις τ' | ἀπόβλεπτος μέτα.*

For an account of the other iambic metres employed by the Greek and Latin poets, see Hermann, 'Elementa Doctrinæ Metricæ.'

In English poetry the iambic metre is very common; as, for example:—

> "On Lin'den, whe'n the su'n was lo'w,
> All bloo'dless la'y th' untro'dden sno'w,
> And dar'k as win'ter wa's the flo'w," &c.

ICE. In several preceding articles of the present division of this Encyclopædia, reference has been made to the article now commenced for an account of an important fact among the properties of ice, which, from the investigation it has received at the hands of several of the most eminent living men of science, has been elevated almost to the position of a principle in physics. This is the property of REGELATION, by which liquefied ice remaining in contact with ice still solid, returns itself to the solid state.

In the year 1850, Professor Faraday invited attention, in a scientific point of view, to the fact that two pieces of moist ice, when placed in contact, will unite together, even when the surrounding temperature is such as to keep them in a thawing state. He showed experimentally that when two pieces of ice at 32° Fahr., with moistened surfaces, were placed in contact, they became cemented together by the freezing of the film of water between them. When the ice was below 32°, and therefore dry, no adhesion took place between the pieces; and he referred, in illustration of this point, to the well-known experiment of making a snowball. In frosty weather the dry particles of ice will scarcely cohere, but when the snow is in a thawing condition, it may be squeezed into a hard compact mass. He attributed this phenomenon to a property which he supposed ice to possess, of tending to solidify water in contact with it, and of tending more strongly to solidify a film or a particle of water, when the water has ice in contact with it on both sides, than when it has ice on only one side.

To these Professor Tyndall afterwards added the following illustrative facts. "On one of the warmest days of last July [1856], when the thermometer stood at upwards of 80° Fahr. in the shade, and above 100° in the sun, a pile of ice-blocks" being observed in a shop-window, the observer "thought it interesting to examine whether the pieces were united at their places of contact. Laying hold of the topmost block, the whole heap, consisting of several large lumps, was lifted bodily out of its vessel. Even at this high temperature the pieces were frozen together at the places of contact, though the ice all round these places had been melted away, leaving the lumps in some cases united by slender cylinders of the substance. A similar experiment may be made in water as hot as the hands can bear; two pieces of ice will freeze together, and sometimes continue so frozen in the hot water until, as in the case above mentioned, the melting of the ice around the points of contact leaves the pieces united by slender columns of the substance." 'Phil. Trans.,' 1857, p. 329.

Mr. Faraday, in his more recently published 'Experimental Researches in Chemistry and Physics' (being essentially a republication in a collective form of his papers on subjects belonging to those sciences, first published in the 'Philosophical Transactions,' and in several scientific journals), adheres to his original mode of accounting for the phenomenon he had observed, adopting the name Regelation, applied to it by Professor Tyndall. While alluding to certain views of Professor Forbes, which will presently be stated, as possibly being admissible as correct, and to an explanation offered by Professor James Thomson as being probably true in principle, and possibly having a correct bearing on the phenomena of regelation, he considers that the principle originally assumed by himself may after all be the sole cause of the effect. The principle he has in view, he then states as being, when more distinctly expressed, the following:—"In all uniform bodies, possessing cohesion, that is, being either in the liquid or the solid state, particles which are surrounded by other particles having the like state with themselves tend to preserve that state, even though subject to variations of temperature, either of elevation or depression, which if the particles were not so surrounded, would cause them instantly to change their condition." Referring to water in illustration, he says that it may be cooled many degrees below 32° Fahr., and still retain its liquid state; yet that if a piece of the same chemical substance—ice, at a higher temperature, be introduced, the cold water freezes and becomes warm. He points out that it is certainly not the change of temperature which causes the freezing, for the ice introduced is warmer than the water; and he says he assumes that it is the difference in the condition of cohesion existing on the different sides of the changing particles which sets them free and causes the change. Exemplifying, in another direction, the principle he is propounding, he refers to the fact that water may be exalted to the temperature of 270° Fahr., at the ordinary pressure of the atmosphere, and yet remain water, but that the introduction of the smallest particle of air or steam will cause it to explode, and at the same time to fall in temperature. He further alludes to numerous other substances, such as acetic acid, sulphur, phosphorus, alcohol, sulphuric acid, ether, and camphine, which manifest like phenomena at their freezing or boiling points to those referred to as occurring with the substance of water, ice, and steam; and he adverts to the observed fact, that the contact of extraneous substances with the particles of a fluid usually sets these particles free to change their state, in consequence, he says, of the cohesion between them and the fluid being imperfect; and he instances that glass will permit water to boil in contact with it at 212° Fahr., or by preparation can be made so that water will remain in contact with it at 270° Fahr., without going off into steam, but that an ordinary piece of glass will set the water off at once to freeze.

Professor Faraday afterwards comes to a point in his reasoning which he admits may be considered as an assumption. It is, "that many particles in a given state exert a greater sum of their peculiar cohesive force upon a given particle of the like substance in another state than few can do; and that as a consequence a water particle with ice on one side and water on the other, is not so apt to become solid as with ice on both sides; also that a particle of ice at the surface of a mass [of ice] in water is not so apt to remain ice as when, being within the mass, there is ice on all sides, temperature remaining the same."

"This supposition," Professor James Thomson observes, "evidently contains two very distinct hypotheses. The former, which has to do with ice and water present together, I certainly do regard as an assumption unsupported by any of the phenomena which Mr. Faraday has adduced. The other, which has to do with a particle of ice in the middle of continuous ice, and which assumes that it will not so readily change to water, as another particle of ice in contact with water, I think is to be accepted as probably true. I think the general bearing of all the phenomena he has adduced, is to show that the particles of a substance when existing all in one state only, and in continuous contact with one another, or in contact only under special circumstances with other substances, experience *a difficulty of making a beginning of their change of state,* whether from liquid to solid, or from liquid to gaseous, or probably also from solid to liquid; but I do not think anything has been adduced showing a like difficulty as to their undergoing a change of state when the substance is present in the two states already, or when a beginning of the change has already been made. I think that when water and ice are present together, their freedom to change their state on the slightest addition or abstraction of heat, or the slightest change of pressure, is perfect. I therefore cannot admit the validity of Mr. Faraday's mode of accounting for the phenomena of regelation."

The view of the subject involved in the statement of Professors Faraday and Tyndall, given above (before the former had enunciated his own views in the more extended form), was adopted by the latter physicist as the basis of a theory by which he proposed to explain the viscosity or plasticity of ice previously known to be the quality in glaciers [Glaciers, in Nat. Hist. Div.], in virtue of which their motion down their valleys is produced by gravitation; but which he described as being not true viscosity, but, in brief, as the result of fracture, change of position of the fractured parts, and regelation of those parts in their new position; the term *regelation* being now first given to the fact, the scientific importance of which had been originally pointed out by Faraday.* Professor James Thomson, Queen's College, Belfast, whose first express contribution to the subject we now have to record, conceiving Professor Tyndall's theory of the viscosity of glacier ice to be wrong, made public a theory of his own involving a different view of the nature of the phenomenon of regelation. This, as sketched in outline by himself, is as follows:—If to a mass of ice at its melting-point, pressures tending to change its form be applied, there will be a continual succession of pressures applied to particular parts—liquefaction occurring in those parts through the lowering of the melting-point by pressure—(experimentally demonstrated in 1850 by Professor William Thomson, of Glasgow, his brother)—evolution of the cold by which the so melted portions had been held in the frozen state,—dispersion of the water so produced in such directions as will afford relief to the pressure,—and recongelation, by the cold previously evolved, of the water on its being relieved from this pressure: and the cycle of operations will then begin again; for the parts recongealed, after having been melted, must in their turn, through the yielding of other parts, receive pressures from the applied forces, thereby to be again liquefied and to proceed through successive operations as before.†

Professor James D. Forbes adopts the view of Persoz, that the dissolution of ice is a *gradual,* not a *sudden,* process, and so far resembles the tardy liquefaction of fatty bodies, or of the metals, which in melting pass through intermediate stages of softness or viscosity.‡ He thinks that ice must essentially be colder than water in contact with it; that between the ice and the water there is a film varying in local temperature from side to side, which may be called plastic ice, or viscid water; and that through this film heat must be constantly passing from the water to the ice, and the ice must be wasting away, though the water be what is called *ice-cold.* On this, Professor J. Thomson thus comments:—"There is a manifest difficulty in conceiving the possibility of the state of things here described; and I cannot help thinking that Professor Forbes has been himself in some degree sensible of the difficulty; for in a note of later date by a few months than the paper itself [in which the view had been given], he amends the expression of his idea by a statement to the effect that, if a small quantity of water be inclosed in a cavity in ice, it will undergo a gradual *regelation* [§],—that is, that the ice will in this case be gradually increased instead of wasted." In reference to the first case, Professor J. Thomson asks, "What becomes of the cold of the ice, supposing there to be no communication with external objects, by which heat might be added to or taken from the water and ice jointly considered? Does it go into the water and produce viscidity beyond the limit of the assumed thin film of viscid water at the surface of the ice? Precisely a corresponding question may be put relatively to the second case,—that of the large quantity of ice inclosing a small quantity of water, in which the reverse process is assumed to occur. Next, let an intermediate case be considered, that of a medium quantity of ice, and in which no heat nor cold, practically speaking, is communicated to the water or the ice from surrounding objects. This, it is to be observed, is no mere theoretical case, but a perfectly feasible one. The result, evidently, if the previously described theories be correct, ought to be that the mixture of ice and water ought to pass into the state of uniform viscidity. Professor Forbes' own words distinctly deny the permanence of the water and ice in contact in their two separate states; for he says, 'Bodies of different temperatures cannot continue so without interaction. The water must give off heat to the ice; but it spends it in an insignificant thaw at the surface, *which, therefore, wastes even though the water be what is called ice-cold.'* Now, the conclusion arrived at, namely, that a quantity of viscid water could be produced in the manner described, is, I am satisfied, quite contrary to all experience. No person has ever, by any peculiar application of heat to, or withdrawal of heat from, a quantity of water, rendered it visibly and tangibly viscid. We even know that water may be cooled much below the ordinary freezing point and yet remain fluid."

---

* The terms *fracture* and *regelation,* Professor J. Thomson remarks, then came to be the brief expression of Professor Tyndall's idea of the plasticity of ice. But the former, whose views we are about to give in the text, observes on the nomenclature of the process, "I suppose the term regelation has been given by Professor Tyndall as denoting the second, or mending stage in his theory of '*fracture* and *regelation.*' Congelation would seem to me the more proper word to use after fracture, as *regelation* implies previous melting. If my theory of *melting by pressure and freezing again by relief of pressure* be admitted, then the term regelation will come to be quite suitable for a part of the process of the union of the two pieces of ice, though not for the whole, which then ought to be designated as the process of *melting* and *regelation.*" 'Proceedings of the Royal Society' (vol. x.) for Nov. 24, 1859, p. 154, note. It may be remarked on this, however, that while the latter phrase may be required in discussing the phenomena of glaciers, as the word *re*-gelation itself implies that a previous frozen state has existed, it would appear to be sufficient in designating simply the physical process to which it was originally applied.

† In explanation of the simplest case of regelation, Professor J. Thomson expressed himself in the following manner in a communication to the British Association, in 1857:—"The two pieces of ice (at 32°) on being pressed together at the point of contact, will, at that place, in virtue of the pressure, be in part liquefied and reduced in temperature, and the cold evolved in their liquefaction will cause some of the liquid film intervening between the two masses to freeze."

‡ Sir J. F. W. Herschel, when he terms regelation "a sort of welding" (Hail), appears to concur with this view.

[§ This use of the term *regelation* we conceive to be at once inaccurate, and tending to ambiguity. The water in this case need not have been frozen before; and to call its solidification, by the effect of the contiguous ice, regelation, is erroneously to extend the application of that term to all cases in which water, however originally resulting, is frozen by the contact of ice.]

Professor Forbes regards Mr. Faraday's fact of regelation as being one which receives its proper explanation through his theory described above; and, in confirmation of the supposition that ice has a tendency to solidify a film of water in contact with it, and in opposition to the theory given by Professor J. Thomson, that the regelation is a consequence of the lowering of the melting-point in parts pressed together, he adduces an experiment made by himself. He states that mere contact without pressure is sufficient to produce the union of two pieces of moist ice, and then describes as follows his experiment by which he supposes that this is proved:—"Two slabs of ice, having their corresponding surfaces ground tolerably flat, were suspended in an inhabited room upon a horizontal glass rod passing through two holes in the plates of ice, so that the plane of the plates was vertical. Contact of the even surfaces was obtained by means of two very weak pieces of watch-spring. In an hour and a half the cohesion was so complete that, when violently broken in pieces, many portions of the plates (which had each a surface of twenty or more square inches) continued united; in fact, it appeared as complete as in another experiment, where similar surfaces were pressed together by weights." He concludes that the effect of pressure in assisting "regelation" is principally or solely due to the larger surfaces of contact obtained by the moulding of the surfaces to one another.

Professor J. Thomson has himself repeated this experiment, and has found the results described by Professor Forbes to be fully verified. It was not even necessary to apply the weak pieces of watch-spring, as he found that the pieces of ice, on being merely suspended on the glass rod in contact, would unite themselves strongly in a few hours. This fact Professor Thomson explains by the capillary forces of the film of interposed water, as follows:—Firstly, the film of water between the two slabs—being held up against gravity by the capillary tension or contractile force of its free upper surface, and being distended besides, against the atmospheric pressure, by the same contractile force of its free surface round its whole perimeter, except for a very small space at bottom, from which water trickles away, or is on the point of trickling away—exists under a pressure which, though increasing from above downwards, is everywhere, except at that little space at bottom, less than the atmospheric pressure. Hence the two slabs are urged towards one another by the excess of the external atmospheric pressure above the internal water pressure, and are thus pressed against one another at their places of contact by a force quite notable in its amount. If, for instance, between the two slabs there be a film of water of such size and form as might be represented by a film one inch square, with its upper and lower edges horizontal, and with water trickling from its lower edge, it is easy to show that the slabs will be pressed together by a force equal to the weight of half a cubic inch of water. But so small a film as this would form itself, even if the two surfaces of the ice were only very imperfectly fitted to one other. If, again, by better fitting, a film be produced of such size and form as may be represented by a square film with its sides 4 inches each, the slabs will be urged together by a force equal to the weight of half a cube of water, of which the side is 4 inches; that is, the weight of 32 cubic inches of water, or 1·15 pound, which is a very considerable force. Secondly, the film of water existing, as it does, under less than atmospheric pressure, has its freezing-point raised in virtue of the reduced pressure. Much more, he adds, will it freeze in virtue of cold given out in the melting by pressure of the ice at the points of contact, where, from the first two causes stated above, the two slabs are urged against one another.

The different explanations and interpretations which have been enunciated of the facts of regelation have been stated in this article partly in the words of their authors, and partly in those of Professor James Thomson, by whom the subject has been most recently treated. References to some of the original memoirs will be found in his paper in the 'Proceedings of the Royal Society' (vol. x.), for Nov. 24, 1859, pp. 152–160; and others will be indicated in the sequel of this article.

It is manifest that the subject of regelation is one of great importance in physics and in the history of nature, being connected with that of the mutual relations of the different states of aggregation in which the same species of ponderable matter—the same substance, chemically speaking—can exist, and also with those "hidden and unseen motions," to use the language of Boyle, by which the molecular condition of such matter is perpetually changing. Some bodies, the equilibrium of the proximate elements of which is very unstable, present, in the solid state, phenomena, seemingly at least, analogous to those presented by water, and others in their alternation between the liquid and the solid states. Of these, glass is an example, and the now well-known fact of the incorporation into one mass of two or more plates of (plate-) glass, the polished surfaces of which have been placed in close contact with each other, presents a curious parallel to the incorporation into one of several slabs or other separate portions of ice by regelation, as taking place in the experiments described in this article, and to determine in what manner these two subjects are related to each other would appear to deserve careful investigation. The principal facts, so far as glass is concerned, with the bearings on molecular philosophy they appeared to possess before the phenomena of regelation had been scientifically considered, will be found in the abstracts of two lectures on that substance delivered by Mr. Brayley before the Pharmaceutical Society of London in 1845, published in the 'Pharmaceutical Journal' (vol. v.) for August and October of that year.

In a paper on the Physical Properties of Ice, Professor Tyndall has shown that when a sunbeam traverses a mass of ice, the latter melts at innumerable points in the track of the beam, and that each portion melted assumes the form, not of a globule, but of a flower of six petals. The planes in which these flowers are formed are independent of the shape of the mass, and of the direction of the beam through it; they are always formed *parallel to the surface of freezing*. This, he observes is a natural consequence of the manner in which the particles of ice are set together by the crystallizing force. By the slow abstraction of heat from water in the process of freezing, its particles build themselves into these little stars, and by the introduction of heat into a mass so built, the architecture is taken down in a reverse order. In watching the formation of artificial ice, by the machine of Mr. Harrison (noticed under FREEZING-APPARATUS), Professor Tyndall has seen little solid stars formed, which were the exact counterparts of the little liquid stars formed by melting. 'Phil. Trans.' 1858, pp. 211–227; Ib. 1859, pp. 298, 299. Appended to the former paper is a letter from Professor Faraday on the irregular fusibility of ice.

Another important part of the history of ice is its production on the bed of rivers, when it receives the name of *Ground-ice*, *Bottom-ice*, and *Ground-gru*; the *Glace-du-fond* of the French, and the *Grund-eis* of the Germans. It is generally imagined that rivers freeze only at the surface; this however is not the fact, ice being frequently formed at the bottom of running water. Thus, according to the late Rev. Dr. Farquharson, F.R.S., the phenomenon is so common, and so well known in certain parts of Aberdeenshire, that the inhabitants have given it the name of Ground-gru, a name which that gentleman has adopted in his paper on the subject in the 'Philosophical Transactions' for 1835, p. 329. Gru is the name by which the people of Aberdeenshire designate snow saturated with or swimming in water; and as the ice formed at the bottom of rivers very nearly resembles that in appearance, a better name than Ground-gru could hardly be given, though it would be more precise to call it subaqueous ice, in contradistinction to that found at the surface, and because the term ground-ice, which this formation has also received, has been sometimes given to the ice occasionally met with at certain depths in the ground in northern countries.

Common, however, as may be the phenomenon of subaqueous ice, and although it has been noticed at various times, it has but lately attracted the serious attention of observers. Ireland, in his 'Picturesque Views of the River Thames,' published in 1792, 2 vols. 8vo., mentions the ground-ice of that river, and on the subject quotes Dr. Plott, who says, "The watermen frequently meet the ice-meers, or cakes of ice, in their rise, and sometimes in the underside enclosing stones and gravel brought up by them *ab imo*."

M. Arago published an interesting paper on the subject in the 'Annuaire du Bureau des Longitudes' for 1833, in which he mentions the following observations made on ground-ice:—In the Thames, by Hales, in 1730; in the river Déome, department of Ardèche, France, by Desmarets, in 1780; in the Elbe, by M. Braun, in 1788; in the Teine, Herefordshire, by Mr. T. A. Knight, in 1816; in the Canal de la Birze, near Bâle, by M. Mérian, in 1823; in the Aar, at Soleure, by M. Hugi, in 1827 and 1829; in the Rhine, at Strasburg, by Professor Fargeau, in 1829; and in the Seine, by M. Duhamel, in 1830. More lately still, Colonel Jackson, in a paper on the congelation of the Neva, published in the 5th volume of the 'Journal of the Royal Geographical Society,' mentions the formation of ground-gru at the bottom of that river; and in the 6th volume of the same journal there is a paper expressly on the ice formed at the bottom of the Siberian rivers. The Rev. Mr. Eisdale has, in the 'Edinburgh New Philosophical Journal,' vol. xvii., p. 167, a paper on ground-ice; and, finally, Dr. Farquharson, as already mentioned, published his observations on the ground-gru of the rivers Don and Leochal, in Aberdeenshire.

Almost all who have written on ground-gru have endeavoured to account for its formation, though no explanation yet given is perfectly satisfactory. Dr. Farquharson, whose paper contains an original investigation of the subject, says it is the result of radiation, and endeavours to substantiate his reasoning upon the principles of the formation of dew. It was remarked in this article, as originally published, that he seems to forget that Dr. Wells maintains expressly that wind and shade are alike obstacles to radiation; and that consequently a body of moving water so deep as to be impervious to light, and particularly when covered, as in the case of the Neva, with a sheet of ice three feet thick, and as much more of snow, must present an insurmountable obstacle to the radiation of heat from the bottom of the river. This objection, however, is unsound, and is removed, as in many other instances of the supposed insufficiency of the principle of radiation to account for depression of temperature, by an adequate consideration of the entire series of the phenomena concerned. It is true that the thick sheet of ice and its covering of snow will present an obstacle to the direct radiation of heat into space from the bed of the river, though they themselves will have such radiation above. But the bed of the river, at a comparatively high temperature, will suffer refrigeration by the radiation of its heat to the ice on the surface of the river, and may thus (and if there be time enough must necessarily thus) be cooled eventually to the freezing point, and so effect the formation of the ground-ice. A familiar and readily intelligible illustration of this will be found in an observation of Dr. Joseph D. Hooker, which occurs in the invaluable collection of physical facts presented by his 'Himalayan Journals,' and already cited in the article Dew. When in the narrow valleys of East Nepal, in the month of November, and at the elevation of 8000 feet, the nights were so brilliant, and the radiation from the earth and bodies upon it consequently so powerful, that the upper blanket of his bed became coated with dew, from the rapid abstraction of heat by its radiation to the tarpaulin of his tent, itself frozen by it's own radiation to the sky. The direct radiation of the blanket to the sky was prevented by the tarpaulin, but this did not prevent the conversion of the aqueous vapour in contact with the blanket into dew. In this case, the frozen tarpaulin corresponded in its action to the surface-ice of the river, the blanket to the river-bed, and the dew upon it to the ground-ice. Had the exposure been longer continued, or the temperature of the whole system of radiating bodies been lower, hoar-frost instead of dew would have been formed, and the parallel would then have been perfect,—according to Dr. Farquharson's view of the origin of ground-ice.

Mr. Eisdale thinks ground-ice is the result of frozen spiculæ from the atmosphere, analogous to hoar-frost, falling into the river, and there forming *nuclei*, around which the water freezes at the bottom; but this is quite inadmissible. M. Arago's explanation in part, and the very simple fact that water, when at 32° of Fahr., if at rest, or in very slow motion (which is the case at the bottom of rivers), will freeze, seem among the most natural ways of accounting for the formation of ground-gru. M. Arago attributes the formation to three circumstances—1st, the inversion, by the motion of the current, of the hydrostatic order, by which the water at the surface cooled by the colder air, and which at all points of the temperature of water under 39° Fahr. would, in still water, continue to float on the surface, is mixed with the warmer water below; and thus the whole body of water to the bottom is cooled alike by a mechanical action of the stream; 2nd, the aptitude to the formation of crystals of ice on the stones and asperities of the bottom in the water wholly cooled to 32°, similar to the readiness with which crystals form on pointed and rough bodies in a saturated saline solution; 3rd, the existence of a less impediment to the formation of crystals in the slower motion of the water at the bottom than in the more rapid one near or at the surface. But, as has been said, no explanation yet given is quite satisfactory, and the phenomenon yet remains to be studied under all the variety of circumstances which may attend it. A knowledge of the temperature of the water at different depths is most essential to a just appreciation of the real cause of the phenomenon.

Ground-gru differs materially from surface-ice. Dr. Farquharson describes it as having "the aspect of the aggregated masses of snow, as they are seen floating in rivers during a heavy snow-shower; but on taking it out of the water, it is found to be of a much firmer consistence than these: it is a cavernous mass of various sized, but all small, pieces or crystals of ice, adhering together in an apparently irregular manner by their sides, or angles, or points, promiscuously; the adhesion varies according to circumstances." This corresponds precisely with what is stated by Col. Jackson to have been observed by him in the Neva at St. Petersburg. Dr. Farquharson says, that when it begins to form at the bottom, it aggregates in forms somewhat resembling little hearts of cauliflower. Mr. Weitz, author of the paper in the 'Journal of the Geographical Society' on the ground-gru of the Siberian rivers, says that which he noticed at the bottom of the Kann (an affluent of the Jenissel), 40 versts from Krasnojarsk, was of a greenish tinge, and resembled patches of the *confervoidæ*. From these facts we conclude that though the appearances of the ground-gru may vary with circumstances, it is in all cases essentially different from the solid compact sheets of surface-ice.

[Dew; Freezing; Hail; Hoar-Frost; Meteorology; Snow; Water.]

ICEBERG. [Sea.]

ICE-HOUSES AND ICE-TRADE. Considering ice as an article of commerce, one of the most important points connected with it is the adoption of means for preventing the substance from melting away in hot weather. Ice-houses are expressly constructed to this end. Such structures are not only useful for preserving ice which is to be applied to the cooling of liquors, or to the preparation of articles of confectionary, but also as affording the most ready if not the most effectual means known for keeping meat, fish, game, vegetables, and fruit sweet and fresh in hot weather. Although these important conveniences are rarely to be found among the buildings of an English farm, they are frequent in those of North America, and might be advantageously introduced in this country, especially upon such farms as are connected with inns.

One of the simplest modes of preserving ice consists in enveloping it in a great quantity of straw, above the surface of the ground, in such a position that moisture, which is even more injurious than heat, may drain off freely. For this purpose the ground should be raised in the form of a flattened cone, upon which should be laid a stratum of faggots. Straw is laid upon the faggots to the thickness of a foot or more, and the ice is piled upon it in a compact conical mass, the larger the better. Over the ice is laid first about a foot thickness of straw; then faggot-wood to a further thickness of two feet, the interstices of which have the effect of keeping a stratum of confined air round about the pile of ice; and, finally, two or three feet of straw arranged as a thatch.

An underground ice-house may be simply a large cellar, with hollow or double walls, floor, roof, and doors, and furnished with a trapped drain to allow the escape of such water as may be produced by a partial thaw, without admitting any air. Such ice-houses are usually formed in the shape of an inverted cone, which is considered the most advantageous because it keeps the ice more compactly together than any other form, and because, in case of any thaw taking place, the remaining ice will naturally slip down, so as to keep the mass solid. In all cases it is well to interpose a layer of straw, reeds, or chaff (the last named is preferred to straw in Italy, where it is used for packing ice for travelling) between the walls and the ice; and by the use of faggots as well as straw any perfectly dry cellar in a suitable situation may be used as an ice-house. In some situations a sufficient degree of hollowness in the walls may be produced by the adoption of the plan of building with bricks on edge, or by some similar contrivance. One mode of building hollow walls which may be thus applied consists in the use of half-bricks divided longitudinally, as stretchers, leaving a space equal to the full width of a brick between them. Hollow floors for ice-houses may be constructed in various ways, with bricks on edge and tiles or flags. Whatever be the construction of the ice-house itself, there should be no opening by which it can communicate with the external air excepting through the entrance passage, which is usually at least two or three yards long, and furnished with two, three, four, or more doors, of which not more than one must be opened at a time. Where the difficulty of excluding external temperature is very great, treble walls, roofs, and floors may be used; and the entrance-passage may be made crooked, with a door at every turn.

Loudon gives a ground-plan and section of a complete ice-house of approved construction, of the inverted conical shape, with an arched roof, which it is proposed to cover with two or three feet of earth, or more in hot climates, over which he suggests the propriety of training ivy, for the sake of excluding solar heat. In this design a small pump is shown communicating with a well in the drain of the ice-house, for the purpose of raising the thaw-water for drinking or other use. Ure describes a similar structure, but with solid walls and a conical roof of timber, which may be simply thatched, or covered with brickwork and thatched, and which should have a gutter round it to collect and conduct to a distance all rain that falls upon it. In Gordon's plan the excavation is made considerably larger than the ice-house, which consists of a framework of strong timbers, roughly boarded outside, and lined with straw set on end and confined by laths nailed to the timbers. The conical roof is thatched with straw or heath, and the space between the outer boarding and the surface of the excavation is filled with heath, brushwood, or fir-tops, and neatly thatched or turfed over. In some situations simple excavations in calcareous soils, with a long circuitous passage by way of approach, are used instead of more regular ice-houses.

In filling an ice-house, the ice should be broken with mallets to a coarse powder, and well rammed down as it is thrown into the ice-well; its upper surface being kept of a concave shape, and a little water being occasionally added to fill up all interstices, and to facilitate the congelation of the whole into a solid mass. A better method is to sprinkle the ice with water saturated with salt, at the rate of a pound of salt to a gallon of water. This salt and water may be applied by a common watering-pot upon the surface of the ice at intervals of two feet from bottom to top of the mass, an extra quantity being poured on when the filling is completed. By this means the ice becomes so firmly compacted as to need the force of a pickaxe to break it up, even in the heat of summer. Snow is occasionally preserved in a similar manner to ice, it being carefully compressed into a solid mass. In Portugal and some other countries, when the snow has been collected in a deep gulf, some grass or green sods, covered with dung from the sheep-pens, is thrown over it; and under this covering the snow is so well preserved that it may be taken up and transported to a considerable distance throughout the summer.

An ice-box, or sort of portable ice-house, is occasionally used. It consists of an inner and outer casing, six inches apart, the interval between which is filled with burnt cork reduced to powder, this being found to possess higher non-conducting properties than the charcoal of wood. The lid is double, and is filled with the same substance; and it is made perfectly air-tight by means of projecting ledges, which, when shut, dip into a gutter filled with water. Ice may be preserved for several weeks in such a box, in which also bottles, dishes, &c., may be placed. Similar to this contrivance is the American ice-safe, introduced a few years ago into this country.

The French, in 1859, constructed an extensive range of ice-houses in the Bois de Boulogne, between the Auteuil railway and the fortifications of Paris. During the hard frost of December in that year, 250 carts were employed for 10 days in conveying ice to these buildings.

A remarkable traffic has sprung up in America, namely, the transport of ice to various parts of the world. In the East Indies the artificial formation of ice has been long carried on, as the only means of cooling beverages and food. The ground near Hoogly, about 40 miles from Calcutta, is formed into shallow troughs; into these troughs, on a layer of straw, are placed pans of porous earthenware. Shortly before midnight in the winter months, and when the wind happens to be blowing from the north-west, a little water is poured into each vessel or pan; and if all the circumstances are favourable, a film of ice is found in each pan on the following morning, which ice is collected and stored with the utmost care. The selling price of this ice at Calcutta was formerly about sixpence per pound; but the Calcutta inhabitants were surprised by the arrival, in 1833, of a ship from the United States, laden entirely with ice, which was offered for sale at three-pence per pound, and was understood to yield a good profit, even after paying all the expenses of a long voyage. Since then the price has been much lowered, and ice has become a regular article of shipment from America. The idea of this trade had occurred to a Boston merchant, Mr. Tudor, twenty years earlier; but it was only by much patience and perseverance that he overcame the various difficulties.

The trade is now chiefly in the hands of the Wenham Lake Company. This company purchased a lake of pure water, and the surrounding land, at Wenham, about eighteen miles from Boston; they built storehouses, and formed a railway from Wenham to Boston. The lake is very deep, and is supplied solely by springs, which issue from its bed. During winter the ice which forms on it is very thick, clear, and compact. When the ice is about a foot thick, a number of men, horses, and machines are set to work. The ice is first swept scrupulously clean; an *ice-plane* is drawn over it, to cut away a layer of loose or imperfect ice; an *ice-plough* is drawn over it, to cut a groove across the lake; and other machines are successively employed, until the ice is removed from the lake, in solid blocks weighing from one to two cwts. each. They take two acres of lake surface into operation at one time; this will yield, at the average thickness, about two thousand tons of ice; and forty men, assisted by twelve horses, will cut and stow four hundred tons of this in a day. The company's store-house, near the lake, is built of wood, and has double walls two feet apart: the intervening space being filled with sawdust; twenty thousand tons of ice can be stored in this building at one time. The company convey the ice to Boston on their own railway, and thence transmit it to various parts of the world. Large store-houses have been formed in many parts of the United States, as well as in London and Liverpool. So many are the establishments now engaged in this trade, and so important has it become, that the ice-farms of the states of Massachusetts and New York are reputed to be equal in commercial value to the rice farms of Georgia. Boston is the great storehouse, containing sometimes as much as 300,000 tons of ice in store at once. About 10,000 persons altogether are supposed to be concerned in and with the ice-trade of America, and about 6,000,000 dollars of invested capital.

A curious project was started a few years ago, for sending a steamboat to Newfoundland, to *tow home an iceberg*; an iceberg of 10,000 tons would, it was conceived, pay the expenses and yield a good profit.

There have been many projects for producing ice artificially—by rarefaction, by evaporation, by the contact of freezing mixtures, and by other means; some of which are described in the articles Freezing; Freezing Apparatus; Freezing Mixtures.

ICELAND MOSS, botanically *Cetraria Islandica: Medical Properties of.*—This lichen, commonly termed Iceland moss, though native of the higher mountains of the northern part of Britain, is procured mostly from Norway and Iceland, on the lava of the west coast of which latter country it abounds and attains a large size. It is imported through Hamburg. "The thallus is erect, tufted, olive-brown, paler on one side, laciniated, channelled, and dentato-ciliate; the fertile lacinia very broad; apothecia brown, appressed, flat, with an elevated border." (Hooker.) The apothecia are very rarely developed on the thallus in Britain, save on the mountains of Ben-na-bord in Aberdeenshire, and the imported specimens rarely have them, probably from being gathered in a young state; for this lichen is too important an article of food in northern countries to be allowed to grow to maturity. When dry, it has scarcely any odour, and the taste is bitter and unpleasant. The powder or flour is of a whitish gray.

The analysis of Berzelius gives as its constituents—starchy matter of a peculiar kind (*lichenin*), 44·6; bitter principle (*cetrarin*), 3·0; uncrystallisable sugar, 3·6; chlorophylle, 1·6; extractive matter, 7·0; gum, 3·7; bitartrate of potass, and tartrate of lime, along with phosphate of lime, 1·9; amylaceous fibrin, 36·2; and inulin.

The bitter principle, or cetrarin, may be separated by digesting the lichen in cold water containing 1-16th of carbonate of potass (some affirm 1-300th to be sufficient) for twenty-four hours. The whole is then thrown upon a sieve, and the liquid drained off. This liquid, when evaporated, yields a whitish principle, extremely bitter, very soluble in alcohol, particularly when boiling, and ether; sparingly so in water, volatile oils, and creasote. This principle may also be separated by animal charcoal, according to Peretti. ('Annalen der Pharmacie,' vi. p. 344.) If the lichen be steeped in distilled water, and once or twice heated in the water up to 180° Fahr., most of the bitterness is removed. (Pereira.) When this is removed, the starchy matter differs little from wheat-flour in nutritive properties, though Olasson asserts that a soup prepared with it is twice as nutritious as one made with flour. (Sparmann, 'Voyage,' iii. p. 129, note.) Certain it is that the inhabitants of Norway, Lapland, and above all, of Iceland, use it extensively as an alimentary substance, the latter regarding it as the gift of "a bountiful Providence, which sends them bread out of the very stones." Dr. Henderson ('Tour in Iceland') says that a porridge made of this lichen-flour is to a foreigner not only the most wholesome, but the most palatable, of all the articles of Icelandic diet. It is submitted to no other preparation than repeated steepings in cold water, drying, and powdering; after which it is either made into cakes or boiled in milk. Unless it be steeped, it is both offensively bitter, and also to many persons purgative; hence it has been called *lichen catharticus.* (Borrichius, 'Act. Hafnien.,' 1671, p. 126.) But cattle turned out to browse on it in spring, though at first purged, ultimately become fat. (Boerhaave.) Owing to its intensely bitter taste, as it had not been previously steeped, Sir John Franklin, even when pressed by hunger, could not use it, though the tripe de roche suited well. ('First Journey to Shores of Polar Sea,' 4to., p. 413, 414.)

The excellence of Iceland moss depends upon its freshness and freedom from accidental impurities, which should be carefully removed before it is used. In its natural state, that is, while still containing the bitter principle, it is tonic, stomachic, febrifuge, demulcent, and nutritious. It has acquired a high reputation, not merely as an article of diet, but as a medicinal agent in consumption and chronic diarrhœas, and dysenteries devoid of inflammatory states of the intestines. To obtain benefit from it, the use of it must be persisted in for a long time. This constitutes at once a difficulty in the employment of it, and casts a doubt on the exact nature of the cases in which it is said to have proved serviceable. The unpleasantness of the bitter it contains renders it unpalatable to most persons, and also its heating qualities unfit it for those who have either much general fever, or a state of sub-acute inflammation of the stomach, a very frequent condition in genuine phthisis pulmonalis. Hence there is every reason for suspecting that in the instances where it has been used for a long time and proved beneficial, the disease was chronic bronchitis, in which bitters and demulcents are extremely useful. To disguise the disagreeable flavour many expedients have been had recourse to, such as uniting it with chocolate or cocoa, and flavouring it with orange-flower water, &c. (A full account of these may be found in Hufeland's 'Journal,' August, 1824, p. 126, from the pen of Dr. Oppert. Many formulæ may be found in Geiger, 'Pharmacopœia Universalis.') The only officinal form in Britain is the decoction, which is frequently made the vehicle of medicinal agents. Cetrarin has been given in a separate form as a succedaneum for cinchona bark, and, like many other very bitter articles, is of considerable efficiency in agues. Many substitutes for Iceland moss have been proposed; one of the best of which is the Carrageen or Irish moss (*Fucus crispus*). This, when the brackish taste is lessened by repeated steepings in cold water, forms an excellent jelly, much relished by consumptive patients, and much cheaper than any other. The *Sticta pulmonacea*, or lung-wort, is of unquestionable efficacy in some cases of asthma. But none are so palatable as the Ceylon moss (*Fucus amylaceus*). This can be procured not only from Ceylon, but abundantly from the east coast of Bengal. In the form of jelly, soup, lozenges, or other mode of preparation, it not only agrees better, but is more relished than any jelly, either animal or vegetable. It is to be hoped that it will become a regular article of commerce.

All the Iceland moss imported into Britain is not used for medicinal purposes; much is employed in baking ship-biscuits, as those into the composition of which it enters are said not to be attacked by worms, or suffer much from sea-water. In Saxony, in time of scarcity, it is advantageously added to wheaten flour. In some countries it is employed in brewings.

ICHNOGRAPHY (from *ιχνος* and *γραφη*), a representation of the groundwork of a building. The *ichnography* of a building is, in fact, what is more commonly called the plan, or ground-plan: as the *orthography* is the elevation.

ICHTHIN. An albuminous principle extracted from the yolk of the eggs of cartilaginous fishes, such as the ray fish. It has the appearance of white transparent soft grains, insoluble in alcohol, water, and ether. Hydrochloric acid dissolves it without violet coloration, which distinguishes ichthin from albumen. It contains:—

Carbon	50·9
Hydrogen	6·7
Nitrogen	14·7
Phosphorus (?)	1·9

ICHTHIDIN. [Ichthulin.]

ICHTHULIN. An albuminoid substance found along with *ichthidin* in the roe of certain species of fish. It is precipitated by the addition of water to the expressed fluid of the roe. Ichthulin when first precipitated is viscous like gluten, but it afterwards becomes pulverulent. It contains:—

Carbon	52·5
Hydrogen	8·0
Nitrogen	15·2
Sulphur	1·0
Phosphorus (?)	·6

ICICANE. [RESINS.]

ICONOGRAPHY (from εικων and γραφη), a description of images and their attributes. The term iconography applies generally to descriptions of the figures represented in ancient sculpture and painting, but it is frequently restricted to descriptions of the images which are found in monuments of mediæval art. In this sense iconography, or, as it is more accurately designated, Christian iconography, explains and illustrates, by means of written descriptions and pictorial representations, the images, whether historical, legendary, allegorical, or symbolical, of the three persons of the Trinity, the Virgin Mary, saints, angels, demons, animals, and natural objects, which are found represented in the churches, church furniture, carvings, pictures, stained-glass windows, funeral monuments, illuminated manuscripts, &c., from the earliest period of Christian art downwards to the 16th century. Works like E. Q. Visconti's 'L'Iconographie ancienne; ou recueil des portraits authentiques des empereurs, rois et hommes illustres de l'antiquite,' 3 vols. folio, Par. 1808–26; Montfaucon's 'L'Antiquité Expliquée et Representée en Figures,' and Müller's 'Denkmäler der Alten Kunst,' may be quoted as illustrations of the iconography of Greek and Roman art; whilst as examples of Christian iconography we may cite M. Didron's 'Iconographie Chretienne' (vol. i., 4to., 1843), which forms a volume of the 'Collections inédits sur l'Histoire de France,' and of which an English translation has appeared in Bohn's 'Illustrated Library;' the iconographic portion of De Caumont's 'Cours d'Antiquités Monumentales,' Guenebault's 'Dictionnaire Iconographique,' and perhaps Mrs. Jameson's more popular volumes on 'Legendary and Sacred Art.'

The term has also been applied to representations of objects in the animal and vegetable kingdom in a manner which will be best explained by the title of the work of M. Guérin Méneville, 'L'Iconographie du Règne Animal de Cuvier; ou, représentation d'apres nature de l'une des espèces les plus remarkable et souvent non encore figurées, de chaque genre d'animaux. Avec un texte descriptif,' 3 vols. 8vo, Paris, 1829–44.

ICONOLOGY (from εικων and λογος) the explanation of symbols, types and emblems, and of allegorical figures with their attributes. Of this kind are the 'Iconologie par figures; ou Traité complet des Allegories, Emblèmes, &c.,' of M M. Gravelot [H. F. Bourguignon]. and Cochin, 4 vols. 8vo., Paris, 1796; the 'Iconologie historique,' of M. C. Delafosse, 2 vols. folio, Paris, 1768; and the 'Iconologia,' of F. Pistrucci, Milan 1819-21, of which an English translation, in one vol. folio, was published in 1824 under the title of 'Iconology; or the Art of representing by allegorical figures the various abstract conceptions of the mind.' The term is not much used now.

ICOSAHEDRON. [SOLIDS, REGULAR.]

ICTERUS. [JAUNDICE.]

IDEA (ἰδέα, from the root ἰδ, to see), in its widest and now generally received acceptation, is employed to indicate every representation of outward objects through the senses, and whatever is the immediate object of thought. Like many other terms of mental philosophy, it is derived from the most eminent of the senses, that of vision. In the Platonic philosophy, the word idea possessed a higher import, and signified, primarily, the archetypes of all created things as they subsist in the divine intellect; and, secondarily, the conceptions of the human understanding, by means of which the essence of a thing is conceived. According to another, though a more questionable definition, the Platonic ideas denoted certain absolute qualities, which are regarded as real because they are capable of becoming objects of true knowledge. Plato's own definition is very extensive: "an idea may be attributed to whatever, as a plurality, may be indicated by the same name" (εἶδος γάρ πού τι ἕκαστον εἰώθαμεν τίθεσθαι περὶ ἕκαστα τὰ πολλά, οἷς ταῦτὸν ὄνομα ἐπιφερομεν. 'De Rep.' x. 596 a). For in Plato's loose phraseology the terms εἶδος and ἰδέα are employed indifferently in the same sense. This being remembered, there is little objection to Plutarch's historical account of these ideas, which we here give in the English of Holland. "Idea is a bodiless substance, which of itself has no subsistence, but giveth form and figure to shapeless matters, and becometh the cause that bringeth them into show and evidence. Socrates and Plato supposed that these be substances separate and distinct from matter, howbeit subsisting in the thoughts and imaginations of God, that is to say, of mind and understanding. Aristotle admitteth verily these forms and ideas, howbeit not separate from matter, as being patterns of all that God hath made. The Stoics, such at least as were of the school of Zeno, have delivered that our thoughts and conceits are the ideas." (Plutarch, ch. x., fol. 666; 'Opinions of Philosophers.')

Those ideas by means of which perception is obtained were commonly supposed to be really images or resemblances of external objects. By the Peripatetics however they were held to be inmaterial, while Epicurus and his followers made them to partake of the matter as well as of the form of their originals (tenui rerum simulacra). See Cic. 'ad Att Ep.,' ii. 3.) For the term idea the schoolmen employed the word *species*, by which, Cicero tells us, it was usually rendered in Latin ('Top.' 7), although he himself proposed "*form*," which has been in later times adopted by Kant and his followers to designate that constant element in the perception of outward objects which is independent of matter, and which the mind presents to itself in accordance with its own laws. These species the schoolmen divided into sensible and intelligible, of which we shall here extract Hobbes's clear and succinct account. "The philosophy schools teach that for the cause of vision the thing seen sendeth forth on every side a visible species, (in English) a visible show, apparition, or aspect, or a being seen, the receiving of which into the eye is seeing. . . . . Nay for the cause of understanding also the thing understood sendeth forth an *intelligible* species, that is, an intelligible being seen, which coming into the understanding makes it understood." ('Of Man,' part i., c. 1.)

The term idea was again introduced into philosophy by Des Cartes, with whom and his followers it is nearly synonymous with the species of the schoolmen. According to Locke, "Ideas are whatever is the object of the understanding, whatever a man thinks, or whatever it is the mind can be employed about thinking." (Letter to the Bishop of Worcester, 'Works,' vol. iv.) In this large sense the word is generally employed by English and French writers, and also by the Germans before the time of Kant, for the father of the critical philosophy ascribes to idea a higher but limited signification. By idea Kant eminently designated every conception formed by the reason (as distinct from the understanding), and raised above all sensuous perception. These *ideas* he subdivides into, 1st, empirical, which have an element drawn from experience, for instance, organisation, a state, a church; and 2nd, pure, which are totally free from all that is sensible or empirical, such as liberty, immortality, holiness, felicity, deity. Another division of the Kantian ideas is into theoretical and practical, according to a similar division of the reason itself. Thus the idea of truth is a theoretical idea, that of morality a practical idea.

For an account of the various theories, and his opinions of them, no better work can be named than the 'Lectures on Metaphysics' by the late Sir William Hamilton, published under the editorial care of the Rev. H. L. Mansel and J. Veitch, 1859, &c. There is valuable matter also in Sir William Hamilton's editions of the works of Dr. Thos. Reid, and of Dugald Stewart.

IDEAL has two uses, philosophical and critical. In the former it signifies, first, whatever belongs or relates to ideas generally. It is in this sense that the word is employed in the phrase "Ideal theory," in the controversy between Reid and Priestley. According to this theory, the understanding does not perceive external objects themselves by means of the sensuous organs, but the organs of sight and touch transmit to the mind certain ideas or images of sensible objects, which it perceives within itself. Locke, who received the term idea from Des Cartes, seems unconsciously to have adopted, with the use of the word, the scholastic doctrine which it involved. For he expressly declares that our ideas of the primary qualities of bodies are resemblances of them, but that those produced by secondary qualities are no resemblances at all. From this explanation of the means of perception, Locke has, on the one hand, been represented as the origin of modern idealism; while on the other, in consequence of the superior value which he evidently gives to the testimony of sensation, his authority has been claimed by the opposite school of ideology, as founded by the disciples of his French commentator Condillac. The second sense of the word is more limited, being confined to a peculiar class of ideas created by and solely subsisting in the imagination. Connected with this especial signification is its usage in the science of criticism, or æsthetics. Here ideal signifies a something which, although not existing in the reality of sensible things, subsists actually in thought—the joint creation of the reason and the imagination, the archetype and pattern of supreme and perfect beauty. Although unreal in nature, this ideal is not unnatural; it is the absolute sum and unity of those scattered beauties which nature, with a lavish but impartial hand, has diffused among her myriad phenomena. [ÆSTHETICS; BEAUTY.]

IDEALISM, the designation of many and different systems of philosophy, which only agree in the common principle from which they originate. This principle is the opposition of the ideal and the real, that is, of ideas and things—the contrariety of mind and body, or of spirit and matter.

1. As the essence of the mental lies in free activity and vital motion, as opposed to the invariable mechanism and inertness of the corporeal, the name of Idealism is rightly applied to those systems of physiology which make the primal substance and original of all things to be certain forces invisibly working throughout the universe. To the idealists of this class belong the dynamical philosophers of the Ionian school, Thales. Anaximenes, Diogenes of Apollonia, and Heraclitus.

The fundamental position of their several doctrines was the assumption of a living energy which as it developes itself undergoes continuous alteration both of form and quality—a transmutation which is the cause of all generation in nature. For water, the primary substance of Thales, was not the simple element, but water pregnant with vitality; the infinite air of Anaximenes was an animated and animating energy; and the intellectual primary of Diogenes was not merely the atmospheric air, but a warm and perfect breath of life which pervades and ensouls the universe. While however in these philosophers the philosophical idea is more or less mixed up with divers sensible conceptions, Heraclitus seems clearly conscious of speaking figuratively of the primary substance. With him a universal and absolute life is the cause of all phenomena, which indeed is most strongly and openly manifested in the vitality of fire and the rational soul, which is like to fire, while in other phenomena it is inherent, although not so obvious and immediately cognisable. In this class of idealists among moderns we must reckon Boscovich and Leibnitz. The former explained matter to be a system of forces; while, according to the latter, all beings are of the same nature. Activity and simplicity are the essential characters of all, and are so many forces or causes which he terms *monads*. All these monads possess the faculty of *perception*, or of reflecting within themselves, as in a mirror, the universe. These images however of perception cannot become the objects of knowledge, unless in these monads, which possess also what Leibnitz calls apperception, by which they are enabled to distinguish and see in themselves these images. It is therefore this faculty of apperception which constitutes the difference between the so-called material and spiritual; and as the faculty itself admits of different degrees, there are corresponding orders of intelligences. Lastly, we must include in this class, if anywhere among the idealists, the system of Spinoza, who asserts the identity of matter and spirit, making them to be but different aspects of one and the same substance; and Schelling, whose philosophy may be regarded as the complement of that of the Jewish philosopher.

2. Another species of idealism considers the real as simply ideal, and assumes that our representations of a material world correspond to nothing actually existing, but that by contemplating these as objective, we transmute the merely ideal into the real. The fundamental axiom of this idealism is the priority of the ideal and the subsequence of the real ('ideale prius, reale posterius'). Accordingly, the real only exists so far as it is necessarily conceived by us, so that the external world is purely a creation of our conceptions, or, in other words, the real is a product of the ideal. To this class is referred the Platonic attempt to account for the existence of the sensible world by his *ideas* alone, without recourse to any other nature alien and foreign to them. By some, even the Aristotelian philosophy is designated as ideal in this sense, at least so far as regards its fundamental principle. This they make to be the assumption of a universal mundane intelligence (νοῦς), which, as the principle of all things is a force (ἐντελέχεια), self-active, all-perfect, and absolutely free. The manifold manifestations of this entelechy are forms before and beside which matter exists only potentially, while the forms are determined and distinguished by privation (εἶδος, ὕλη, στέρησις). But the most perfect of idealists in this class is Fichte, who derives not merely the form, but also the matter, of the conception of external things out of the mind itself, or, in his terminology, out of the *ego* (Ich).

3. A third system of idealism proceeds to the absolute denial of all material existences. This species of idealism was impossible among the ancients, who did not oppose mind so sharply to matter as to deny the possibility of their interaction, but tacitly supposed their similarity, opposing only corporeity, as composite, to incorporeity, as simple. Of this idealism Bishop Berkeley is the author, although Des Cartes gave occasion to it by his position, that nothing extended can enter the unextended soul. Arthur Collier maintained the same theory, by a different line of argument, and Locke afforded, by his doctrine of ideas, the arguments for its support. The system of Berkeley is briefly this: matter does not exist independently of our sensations, but conceptions of a material world are produced by the operation of the deity upon our understanding, and the material world exists only in the divine intellect, who awakes in us certain sensuous conceptions in a definite order, which order is what we call the course of nature.

4. The last species of idealism is more philosophical, and, without denying or asserting the existence of a material world, is content with confessing an ignorance of its nature. It pretends not to a knowledge of things themselves, but is content with employing the ideas which the mind forms, according to the laws of its own nature, upon the occasion of the excitement of its sensuous organs, without determining whether these ideas correspond or not to the exciting cause or causes, whatever they may be. To this class belong Malebranche and Kant. According to the former, mind and matter cannot act upon each other, and the sensations of the mind are so many occasional causes operating by a constant miracle of divine agency. (*Deus ex Machinâ*) According to the latter, all that we know of outward objects is that they furnish the material part of our conceptions, to which the mind furnishes the form agreeably to its original and connatural laws; while of things themselves, which he calls phenomena, we absolutely know nothing, but note only the modes under which they appear to us.

Idealism in fact forms the antithesis to realism, which involves materialism. Sir William Hamilton in his 'Lectures on Metaphysics' says—"a philosophical system is often prevented from falling into absolute idealism or absolute materialism, and held in a kind of oscillating equilibrium, not in consequence of being based on the fact of consciousness, but from the circumstance that its materialistic tendency in one opinion happens to be counteracted by its idealistic tendency in another; two opposite errors in short, co-operating to the same result as one truth. On this ground is to be explained why the philosophy of Locke and Condillac did not more easily slide into materialism." (Lecture xvi.) He also observes ('Discussions on Philosophy,' &c.) that "mankind in general believe that an external world exists, only because they believe that they immediately know it as existent." But of course if this *knowledge* be disallowed, if the perception be only existent in the mind, the conclusion would be unfounded.

IDENTITY designates in philosophical language the sameness of a substance under every possible variety of circumstances. In this sense it is employed in the phrase *personal identity*, where it signifies the invariable sameness of the thinking subject, or *ego*. In a secondary sense it denotes a merely relative identity, which may also be called logical or abstract. Thus, in logic, whatever things are subjects of the same attribute or collection of attributes are considered the same; for example, dog and lion are the same relatively to the common notion Quadruped, under which they are both contained. Again, in physics, a tree may be asserted to be the same in relation to all the rights of property, notwithstanding the physical change it undergoes from the constant segregation of old and aggregation of new particles. Lastly, it is only in this logical use of the term that we can be said in memory to be conscious of the identity of the reproduced and the original idea, for if they were absolutely identical it would be impossible to distinguish between the first appearance and the recurrence of an idea. (Ancillon.)

According to Butler it is impossible to define the idea of personal identity, but it is easily ascertained; for a comparison of one's self in any two moments of our existence suggests immediately the idea, and at the same time the identity of ourselves. ('Essay on Personal Identity.') Reid's view is nearly similar: "I cannot remember a thing that happened a year ago, without a conviction, as strong as memory can give, that the same identical person who now remembers that event did then exist." ('Essays,' ch. vii.) To the objection that consciousness, being successive, cannot be the same in any two moments, and that therefore, as consciousness constitutes personality, there cannot be any identity of person, Butler answers, that consciousness presupposes and consequently cannot constitute personal identity, and that the object perceived may be the same notwithstanding that the perceptions by which it is discerned are distinct and different. Locke's opinion on this subject appears to have been undecided. "The identity of the same man consists," he says, "in nothing but a participation of the same life, by constantly fleeting particles of matter in succession vitally united to the same organised body." But personal identity he defines to be the sameness of a rational being. (Locke, 'On the Understanding,' p. 2, c. xxviii., s. 6.)

With respect to identical propositions, it is rightly observed "that the greatest assurance and most certain knowledge we can have of any thing is of such propositions as in the schools are called identical." (Sir Kenelm Digby, 'On Man's Soul,' c. ii., p. 28.) For in deductive reasoning the proposition and assumption which make the major and minor premises of the regular syllogism are only logical transmutations of the identical position in physics, that the whole is equal to its parts. Things which are logically identical may be conceived to be so many parts constituting a whole (genus); and the principle, "de omni et nullo" is rightly expanded thus: whatever belongs, or not, to a constituted whole, does or does not belong to all its constituent parts. In the same manner all mathematical propositions are identical; and Aristotle rightly teaches that in these equality is identity (ἐν τούτοις ἡ ἰσότης ἑνότης, 'Metap.' x., c. 3): the ultimate form to which all equations are reduced being $a=a$. It is the want of this identity that constitutes the difference between demonstrative and probable reasoning, although this difference is rather one of degree than of kind; for the inferior certainty in the latter arises from the difficulty of determining, in matters which fall within its domain, what really are all the constituent parts in any whole, or general term; whereas in the former every whole consists of certain determinate and limited parts, so that the procedure to a knowledge of the parts is easy.

By the system of absolute identity is meant the doctrine which teaches the oneness of the subject and object (spirit and matter) as merely different aspects of one substance. This is maintained by Schelling, Hegel, and Cousin, who hold that mind and matter are but "phenomenal modifications of the same common substance," and who reject the conclusion that "the evidence of consciousness to their antithesis is existence."

IDEOLOGY (the science of ideas or mind) is the term by which the later disciples of Condillac, under the Directory and the Empire, have designated the history and evolution of human ideas considered as so many successive modes of certain original or transformed sensations. Proceeding from this exclusive and partial view, nothing perhaps can equal the logical simplicity of the writings of this school, the subtlety of its abstraction, the boldness of its generalisations, or its analytical dexterity in reducing an idea to its simplest expression. Its metaphysical aspect is ably exhibited in the 'Idéologie' of Destutt de Tracy. With him we should also class Main de Biram and Laromiguière, but for the many traces in their writings of dissent from the system, so that they may more properly be considered as forming the transition to that form of mental philosophy in France developed by Royer Collard and his disciples, Jouffroy, and Cousin.

IDES. [KALENDAR.]

IDIOT. [LUNACY.]

IDRIALIN ($C_{30}H_{28}O_2$?), a hydrocarbon found in the mines of Idria. It colours sulphuric acid intensely blue. It is probably identical with *succisteren*, a substance obtained from amber, and which has the same property of colouring oil of vitriol intensely blue.

IDRYL (C_6H_2). A peculiar fusible and volatile hydrocarbon, obtained by the destructive distillation of a kind of coal found in the quicksilver mines of Idria.

IDYLL (Greek, εἰδύλλιον; Lat. *Idy'llium* or *Edy'llium*) is a poem "descriptive chiefly of the processes and appearances of external nature;

or of characters, manners, and sentiments; or of these in conjunction with the appearances of nature. The epitaph, the inscription, the sonnet, and most of the epistles of poets writing in their own persons, belong to this class." ('Preface' to Wordsworth's 'Poems.') In Greek the bucolic poems of Theocritus are called idylls; and all bucolic poetry [Bucolics] may be included under this name; though the ancients did not, any more than ourselves, confine the name to bucolic poetry, as may be seen by referring to the 'Idylls' of Ausonius. In English poetry, the 'Seasons' of Thomson, Shenstone's 'Schoolmistress,' the 'Cotter's Saturday Night' of Burns, the 'Allegro' and 'Penseroso' of Milton, Beattie's 'Minstrel,' Goldsmith's 'Deserted Village,' &c. belong to this class; Mr. Tennyson in his 'Idylls of the King,' has applied the term Idyll in a still more extended sense.

IGASURIC ACID. [Nux Vomica, Alkaloids of.]

IGASURINE. [Nux Vomica, *Alkaloids of.*]

IGNIS FA'TUUS, a meteor resembling a flame, said to float in the atmosphere at a few feet above the surface of the ground. It is stated to be generally observed by night, either stationary or in motion, over marshes or burial grounds; but in the 'Philosophical Transactions,' for 1694, there is an account of some ricks of hay being burnt at Dolgelly, in the preceding year, by a vapour like a weak blue flame which came from the sea. Derham ('Phil. Trans.' 1729) relates that he observed about a decayed thistle a flame in motion, which receded from him as he advanced towards it; and Beccaria states that be saw one which seemed fixed to a spot about two feet above some stones near a river: this philosopher observes that such meteors are most usually witnessed during a fall of rain or snow; he adds that they often appear on clayey soils, and that they have been seen to give out sparks. Trebra ('Deutscher Merkur,' Oct. 1783) mentions that he saw at Zellerfeld a meteor which at first approached him and afterwards receded from him to a distance of 500 paces; he adds that it then disappeared, and at the end of half an hour it again became visible.

Occasionally such meteors have been observed to follow or advance towards a spectator; but in general they appear to recede on being approached, and it has happened that from their resemblance to the flame of a distant lamp, they have led the unwary traveller into dangerous swamps. Little confidence can be placed in the descriptions given of them, as few persons have been able to examine them with due attention; and commonly they have been observed under the influence of an ill-regulated imagination rather than a philosophical spirit.

A plausible hypothesis which has been proposed in order to account for this phenomenon is that a phosphuretted or a carburetted hydrogen gas, produced by the decomposition of animal or vegetable substances, rises from the ground or from stagnant water, either small in quantity and occupying a single spot, or in great abundance and then becoming a train or a horizontal column of vapour of variable dimensions: such gas may take fire by electricity or spontaneously, at a spot where the atmosphere is particularly free from moisture; and the flame communicating itself successively to other parts of a line or column, the latter being in a state of undulation from the agitations of the atmosphere, will give rise to the appearance of a motion from place to place. The brightness of the meteor will change with the varying quantity or purity of the gas; and its temporary disappearance may be caused by the quantity being in some places too small to render the flame visible. Phosphuretted hydrogen would inflame spontaneously on coming into contact with atmospheric air, but no hydrocarbon, it must be objected, is spontaneously inflammable. There is a great dearth of satisfactory observations on moving lights seen in nature, and the entire subject is at present in obscurity. Electrical excitation, true phosphorescence, spontaneous inflammation, combustion otherwise occasioned, may all produce such lights, but whether such causes are really so operative, and whether their effects have been described as *ignes fatui*, remains to be proved.

IGNITION; INCANDESCENCE. These terms refer to that property of bodies, by which they give out light, when raised to certain high temperatures, the quantity of light increasing with the temperature within certain limits. At first it is of a dingy red, or *worm-red* as it is sometimes called; then bright red, indicating what is called a *cherry-red* heat; at a higher temperature we have an *orange* or yellow tint, and lastly a *white heat*, when the light is painful to the eye. Sir Humphry Davy's experiments placed the degree of incipient luminosity in the dark at about 810°, but a dull red visible in daylight is probably equal to 1000°, a full red heat 1200°, an orange heat 1700°, a white heat 3000°, and the high white heat of a good wind furnace (according to Daniell) about 3300°. These remarks apply to bodies which can be raised to these high temperatures without changing their state. Most bodies are dissipated or destroyed before they attain the temperature necessary for ignition, and if heated in the air they inflame and undergo combustion.

I'LEUS, or ILIAC PASSION, is a name given to a severe form of intestinal disease, characterised by violent griping pain around the the umbilicus, spasm and retraction of the muscles of the abdomen, obstinate costiveness, and vomiting. These symptoms are however common to several very different conditions of the bowels; they occur in severe cases of colic [Colic] from spasm, or as some suppose, paralysis of a portion of the intestinal canal, but more commonly they are the result of some mechanical obstruction of the canal, as by intussusception, internal hernia, unnatural adhesions between adjacent folds of intestine, &c. [Hernia.] The treatment must therefore vary according as one or other of these conditions is presumed to exist. In the first class of cases the remedies adapted for colic, combined with active purgatives, should be employed, while in those attended with mechanical obstruction, in which there is always great tendency to inflammation of the intestines, bleeding should be had recourse to, together with purgatives combined with opium, stimulant enemata, and anodynes.

ILICIN, a neutral crystalline vegetable principle, obtained by precipitating a decoction of holly leaves (*Ilex aquifolium*) by di-acetate of lead, evaporating the filtered liquor, and treating the residue with boiling absolute alcohol; by spontaneous evaporation there are produced transparent brownish-yellow crystals, which are bitter, and readily soluble in water, but not in ether. The solution is not precipitated by metallic oxides. This substance has been recommended as a powerful remedy in dropsy and intermittents.

ILLEGAL CONTRACT. [Agreement; Public Policy.]

ILLUMINATING. [Palæography.]

ILMENIC ACID. [Ilmenium.]

ILMENIUM (Il). A mineral first called *Urano-tantalite* has long been known in the neighbourhood of the Ilmen Mountains, in Siberia; but from the fact that it contains no tantalic acid, M. Rose has altered its name to *Samarskite*, it being principally found at Samarski. M. Hermann, however, gives to this mineral the name *Yttro-ilmenite*, asserting that it contains the oxide of a new metal analagous to tantalum, and to which he has given the name *Ilmenium*.

Ilmenic Acid (IlO_2), the binoxide of ilmenium, is the form, according to Hermann, in which the new metal exists in yttro-ilmenite. M. Rose, however, insists that the so-called ilmenic acid is only niobic acid, with a small quantity of tungstic acid, and that a mixture of these latter acids exhibits all the re-actions assigned by M. Hermann to ilmenic acid.

The existence of ilmenium, therefore, as a separate and distinct metal, is not at present satisfactorily established.

IMABENZILE ($C_{28}H_{11}NO_2$). An ammoniacal derivative of benzile. [Benzoic Group, *Benzile.*]

IMAGES, ELECTRIC, OPTICAL, THERMOGRAPHIC, &c. [Breath-figures; Electrical Images; Lens; Light.]

IMAGINARY. [Negative and Impossible Quantities.]

IMAGINATION denotes in its widest sense that faculty of the mind by which it produces at will thoughts or ideas as materials for every other mode of the mental activity. It is often employed in a narrow acceptation as synonymous with fancy, which properly is only a particular species of imagination combined with judgment. Still narrower is the domain of this faculty according to the definition of Dr. Reid, who confines it to a lively conception of the objects of sight, and makes the imagination to differ from conception only as a part from the whole. And similarly Addison teaches that "the pleasures of imagination are such as arise from visible objects, since it is the sense of sight that furnishes the imagination with its ideas." In its widest signification however imagination is coextensive with invention, furnishing the writer with whatever is most happy and appropriate in language, or vivid and forcible in thought. In the same manner it is the imagination that suggests to the scientific inquirer those bold conjectures of analogy or difference which lay open the secrets of nature and multiply its usefulness to man. Indeed, to adopt the language of Dugald Stewart, "All the objects of human knowledge supply materials for her forming hand; diversifying infinitely the work she produces, while the mode of her operation remains essentially uniform."

It is in this illimitable activity that imagination differs from conception, which also is a reproductive faculty, but apparently a mere passive potentiality to bring forth certain given and particular ideas; while the former, when once awakened by the presentation of a single thought, produces out of its storehouse of ideas all the manifold variations of similar and dissimilar. In this procedure, while it is bound indeed by the general laws of association, it is yet free to choose the principle of its combinations. Accordingly every age and every sex, every form of government and of religion, is said to have its special succession; and what is called a knowledge of men consists in nothing else than a knowledge of the train in which their ideas respectively succeed to each other.

A disordered imagination exhibits itself under various forms or characters; as the fantastic, the fanatic, and the enthusiastic.

On the particular character of the imagination depends much of the happiness or misery of the individual. Acting upon human hopes and fears, it assumes the name of sensibility, and by the bright or sombre images with which it fills the distant prospect of life it affords a double relish to every enjoyment or gives a keener edge to sorrow and misfortune.

IMASARATIC ACID. [Indigo.]

IMASATIN. [Indigo.]

IMBECILITY. [Insanity.]

IMESATIN. [Indigo.]

IMIDES. [Organic Bases.]

IMITATIONS, in Music. [Fugue.]

IMMATERIALISM. [Materialism; Berkeley, in Biog. Div.]

IMMORTALITY. [Materialism.]

IMPACT. [Collision, Impact, or Percussion of Bodies.]

IMPEACHMENT. [Parliament.]

IMPENETRABILITY, a name given to the property of matter, the existence of which is suggested when we see that any attempt to place one solid body in the part of space occupied by another is either resisted by the latter, or its success preceded by the removal of the latter. It is then but another name for the cause of that resistance, which we know by the sense of touch, and which is necessary to every idea which we form of matter.

The impenetrability of matter can only be taken in conjunction with the hypothesis of its porosity. Otherwise, it might be successfully disputed. Salt may be dissolved in water without increasing the bulk of the fluid; the (impenetrable?) matter is then penetrated; or else the matter of the fluid has interstices. But if any attempt be made to press the fluid into a smaller space, the impenetrability of the water will appear by its resistance to the pressing substance.

Are we not then making a purely gratuitous introduction of words to supply explanations of phenomena? When matter resists, we have recourse to impenetrability, which is merely saying, so soon as we find resistance, that matter has a power of resisting. But when we ascertain that different portions of matter can be made to fill the same space, whether by solution, pressure, or otherwise, we then appeal to a porosity which we cannot make visible, and presume that matter has empty spaces in which other matter may be placed. This is very much like nature's horror of a vacuum, and other explanations of the same kind.

The answer to this difficulty, and others of a similar kind which occur in attempting to define simple mechanical terms, is that the beginner must not receive them as explanations or as doctrines, but simply as statements of observed phenomena, or at best as terms which imply that explanation is wanted, and serve, till further explanation, to enable us to recal the phenomena themselves and the universality of their existence. Subsequent study and experiment must ascertain the character of this impenetrability, that is to say, the laws of the resistance from which it derives its name. The term is useful to remind us that there is a something which shows itself in all matter; but neither its etymology nor any common notions attached to it must be allowed to dictate any conclusion as to the nature, mode of action, or consequences of that something.

A closer inquiry into the action of matter upon matter shows us that the fundamental notion upon which the above-mentioned something received the name of impenetrability is incorrect. That notion evidently was, that when, for instance, one ball is rolled towards another, the rolling ball absolutely touches the stationary one before it causes motion. There are many circumstances from which it can be inferred, with the highest degree of probability, that such contact is only apparent, and not real. It must be concluded that when the two balls come within a certain small distance of one another, repulsive forces, of the cause and mode of action of which we know nothing, begin to be excited between those particles of the balls which are nearly in contact. It is not our intention in this article to go further into the preceding subject than the mere mention of what are called *molecular* attractions and repulsions, and this merely to point out that the action of matter upon matter must be admitted to commence before the instant at which their surfaces come into contact. [Attraction; Inertia.]

IMPERATOR. [Emperor.]

IMPERATORIN, *Peucedanin*, ($C_{24}H_{12}O_6$), a neutral crystalline vegetable product, procured from the root of the *Imperatoria Ostruthium*: it is obtained by exhausting the root with ether, distilling the greater part of it, and submitting the remainder to spontaneous evaporation, by which the imperatorin is obtained crystallised in prisms, which are colourless, transparent, inodorous, styptic, and acrid; they do not alter vegetable colours; they melt when heated to 167°, and concrete into a radiated mass, the density of which is 1·192. At a high temperature imperatorin is decomposed, diffusing an acrid vapour. It is insoluble in water, but soluble in alcohol, ether, olive oil, and oil of turpentine; when dissolved in a solution of potash, it is precipitated from it by acids, unchanged. Sulphuric acid dissolves imperatorin, and assumes a brownish red colour; in nitric acid it dissolves with a yellow tint: these solutions are both decomposed by water. Iodine forms with it a brownish red compound, which yields iodine when heated.

IMPERMEABILITY, that property by which certain substances resist the passage through their mass of other substances: such, for example, as glass, the pores of which are so small that under no pressure hitherto applied have fluids been driven through them; whereas gold is permeable by water, as in the celebrated experiment of the Florentine Academicians. Some substances are impermeable in consequence of their repulsions to other bodies, such as oilskin or waterproof cloth, which is impermeable to water, in consequence of the repulsion existing between oil and water.

IMPETIGO is a term which has been employed by writers in many independent significations, and for various diseases, but is now confined to a disease of the skin, which Dr. Willan has defined to be "an eruption of yellow itching pustules, appearing in clusters and terminating in a yellow, thin, scaly crust." It is commonly known in this country as the humid or runing tetter, and occurs on all parts of the body, though most frequently on the extremities.

A variety of it is not unfrequently met with in grocers and those much engaged in handling sugar, and to this the term grocer's itch has been applied; but it differs from the itch, properly so called, in its non-contagiousness. [Skin, Diseases of.]

IMPETUS. [Momentum.]

IMPONDERABLE, a term applied to heat, light, and electricity, regarded as *fluids;* but as in modern science they are regarded rather as *forces*, the term has gone out of use.

IMPORTS AND EXPORTS. [Trade and Shipping.]

IMPOSSIBLE. [Negative and Impossible Quantities.]

IMPOST (*Imposta*, Italian), the horizontal mouldings which serve as a sort of cap or cornice to the piers of arches, and on which the archivolts, or curved mouldings and faciæ surrounding the arches themselves, rest. Like these latter the impost is made plainer or richer according to the order employed, or to the general character of the design. And when the archivolts of the arches are omitted, either the impost is omitted likewise, or a plain band is substituted for it. This is generally done in the rusticated basements beneath an order, the joints of the rustics sufficing for decoration, and giving the requisite architectural expression. Imposts, properly so called, are seldom found in pointed Gothic, except in the First Pointed style; but the point of junction between the curve of an arch and its support, however treated, is called the impost. Except in the case above alluded to, the impost is essential in Roman and Greco-Roman architecture. We have, however, a few recent instances in which imposts have been omitted, and the archivolt of the arch continued vertically down the edges of the piers. This was a favourite practice with Soane, both in his designs and many of his executed buildings; and it has been followed by other architects, but the effect is by no means happy.

IMPRESSMENT. [Seamen.]

IMPRISONMENT, FALSE. [False Imprisonment.]

IMPROPRIATIONS. [Benefice; Tithes.]

IMPROVEMENTS, PUBLIC. [Public Improvements.]

IMPROVVISATORI are extempore versifiers who can, without preparation, pronounce a certain quantity of verses upon any given subject. This practice is of frequent occurrence in Italy, and the facilities which the structure of the Italian language affords to versification and rhyme are of great assistance towards it. The improvvisatore delivers his verse, generally accompanied by a guitar, and with a sort of chaunting cadence; and he spins out hundreds, nay at times thousands of lines, with apparent ease: whole dramas have indeed been thus delivered. It must not be imagined however that this kind of extempore poetry is of the best kind; in reality very few of those compositions can stand the test of publication. Still they have the merit of the flow of language and the quick adaptation of accessory ideas and images to the main subject, which rivet the attention and excite the surprise of the listener.

Some improvvisatori have been men of real information and poetical genius, and their compositions are consequently superior. An Augustine friar of the name of Brother Philip, blind and living in the time of Sixtus V., is mentioned as having done wonders in this way. Gianni, of Genoa, a man of considerable poetical talent, was made improvvisatore to the court of the Emperor Napoleon I., with a handsome salary; and Sgricci of Florence became known throughout Europe by giving specimens of his art in the various capitals. Several ladies have distinguished themselves in the same art: they are styled improvvisatrici.

IMPULSE. When a body rolls down a gently-inclined plane we can see the gradual alterations of its velocity, and can readily admit that between the instants at which the body has two different velocities it takes in succession all intermediate velocities, or that the change of velocity is perfectly gradual. But when a body is violently struck, as in the case of a bat and a ball, we can see no gradations of velocity, but the ball appears to be at once altered from a state of rest into one of rapid motion, without having passed through any of the intermediate states. In this case it is said to have received an *impulse*, which word must be interpreted to mean any cause by virtue of which velocity is communicated suddenly and without gradations.

Though the term impulse may be of convenient application to cases of motion in which velocities are changed very rapidly, it must be remembered that the idea of absolutely instantaneous change of velocity is in no degree less absurd than that of a point which is in two different positions at the same instant of time. Impulse, then, must be considered as pressure which, beginning from nothing, increases so rapidly with the time as to produce large effects in a small fraction of a second. Some account of the manner in which impulses act is given in the article Pressure.

It is to be remembered that there is nothing absurd in the idea of any change in the state of a body, provided that a time, no matter how small, be allowed for it to take place in. A cannon-ball now at rest may, in the millionth part of a second, be imagined to have acquired a velocity such as it has when it issues from the mouth of the gun, provided only that a pressure be imagined sufficient to produce the effect. It is only the production of velocity in no time at all which must not be admitted; though it must be owned that the excessive smallness of the times in which some pressures produce a great effect makes us familiar with the notion of impulse, which further inquiry shows us to be a mechanical impossibility as long as the present laws of nature last.

INARCHING. [GRAFTING.]

INCANDESCENCE. The luminous glow of a solid or liquid body intensely ignited. [IGNITION.]

INCENDIARY. [ARSON; LAW, CRIMINAL.]

INCEST. During the Protectorate incest and adultery were made capital offences, but at the Restoration this law was not renewed. Incest in England is now punishable only by the ecclesiastical courts, according to the canon law, which determines what kind of sexual connection is incest. It may be committed either by married persons or persons unmarried. Adultery may be incest, and fornication may also be incest; the legal notion of incest being founded upon the degree of consanguinity or affinity between the parties.

The term is derived from the Roman Incestum, which is the same as Non Castum, "not pure," and in its most general sense signifies any offence against positive morality, or religion. Persons within certain degrees of consanguinity could not contract a marriage; if they did, or lived together as man and wife, such a connection was called incestuous (Incestae Nuptiae). The affecting to marry was not however necessary to constitute Incestum. It existed whenever there was sexual connection between a man and woman who were incapable of contracting marriage. If the parties were capable of contracting marriage, the connection would be Stuprum, which in its limited sense, corresponds to fornication.

The Romans do not appear to have had any direct legislation on this subject till the Imperial period, and the rules of law that were in force were founded upon positive morality and usage. The Lex Julia which was enacted in the time of Augustus treated of incest only indirectly, and so far as it concerned the object of that law, which was the punishment of adultery. In some cases the punishment was capital. (Dion. Cassius, lviii. c. 22; Tacitus, 'Annal.,' vi. 19.)

The subject of the Roman Incestum is treated copiously by Rein, 'Criminalrecht der Römer,' and with a reference to the numerous authorities.

INCH OF CANDLE. [AUCTION.]

INCIDENCE, ANGLE OF, a term used in catoptrics, radiant heat, &c., to express the angle between the direction in which a line strikes on a plane, and the perpendicular to that plane.

INCINERATION. An operation in organic chemistry, which has for its object the separation of inorganic from fixed organic matters. It consists in heating the organic substance to redness in a current of air (in a muffle for instance) until all the organic matter is consumed, the non-volatile inorganic matters are then left behind as an ash.

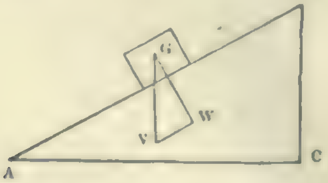
INCLINATION. [MAGNETISM.]

INCLINATION. The inclination of two lines is a phrase commonly used for the angle which they make with one another. Thus, two lines which make a very small angle are said to be at a very small inclination to each other. Looking at the etymology of the word, and its use in common language, it would seem proper to say that one line is without inclination to another when the two are perpendicular, and that the smaller the angle the greater the inclination. But custom has settled otherwise, and has, in fact, made the word inclination synonymous with angle; while the term angle of incidence holds the place which, according to etymology, belongs to angle of inclination.

INCLINED PLANE. Among the mechanical powers, as they are termed, meaning the contrivances by which pressure is advantageously applied, the inclined plane has held a place in practice in every country in which the arts have made any progress. But the introduction of this contrivance into the theory of mechanics dates from the time of STEVIN, to whose life in the BIOG. DIV. we refer for an account of the very remarkable addition which he made to the first principles of statics by means of the inclined plane.

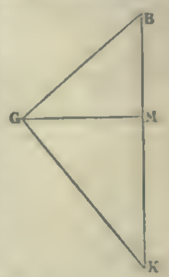
If a weight be placed upon a horizontal plane on which there is no friction, it is obvious that the weight will be entirely supported, and that any horizontal pressure, however small, will cause motion. If the same plane be made vertical instead of horizontal, the weight cannot be placed *upon* it, for if the heavy body were made to touch the plane and then left to itself, it would fall down the plane exactly in the same manner as it would fall if there were no plane; that is, supposing there to be no friction.

If the plane be made to assume an oblique or inclined position, the effect produced will be intermediate between those of the preceding cases. The weight will not rest, nor will it acquire velocity as rapidly as when it falls freely. The reaction of the plane will counterbalance a portion of the weight, as follows:—Let A B represent a section of the plane, and G a section of the weight. Let G V represent the magnitude and direction of the weight, and draw G W and W V perpendicular and parallel to A B. Then [COMPOSITION] the pressure G V is equivalent to the two pressures G W and W V, of which the former is destroyed by the resistance of the plane, and the latter only acts to propel the heavy body down the plane. Now V W is to V G as B C is to A B; that is, a weight placed upon an inclined plane is propelled down the plane by such a fraction of the whole pressure of the weight as the height of any section of the plane is of its length.



If then it were required to draw the heavy body G up the plane, any pressure exceeding V W would be sufficient for the purpose: and a pressure equal to V W, applied in the direction A B, would keep the weight at rest.

If a body which is placed at B on an inclined plane be allowed to fall to G, the velocity which it will then have, and the time of describing B G, are determined as follows:—Let B K be vertical, G M horizontal, and G K perpendicular to B G. Then the velocity at G is that which would be acquired by a body falling freely from B to M; and the time of describing B G would be that in which a body falls freely from B to K. From hence follows immediately the remarkable proposition that if any number of chords be drawn from the highest point of a vertical circle, and if these chords be the sections of as many inclined planes, the times of falling down any two of these chords are the same.



The preceding results are obtained by applying the method explained in the article FALL OF BODIES. Using the notation in that article, and supposing θ to be the angle by which the plane is inclined to the horizon, the accelerating force which urges the weight downwards is $g \sin\theta$. Consequently we have the following equations:—

$$v = g \sin\theta . t. \qquad s = \tfrac{1}{2} g \sin\theta . t^2. \qquad v^2 = 2g \sin\theta . s.$$

Here s is the length B G: and $s \sin\theta$ is B M.

The preceding results suppose friction not to exist: now let there be a friction, the proportion of which to the pressure is the fraction k. Then W representing the weight, the propelling pressure V W is W $\sin\theta$. But the pressure on the plane, or G W, is W $\cos\theta$; consequently k W $\cos\theta$ is the amount of pressure down the plane which friction will resist. If then k W $\cos\theta$ be greater than W $\sin\theta$, that is, if k be greater than $\tan\theta$, the weight will not move; if k be equal to $\tan\theta$, the weight will be just poised, and any pressure, however small, will cause motion; if k be less than $\tan\theta$, the weight will move downwards with an accelerating force $g (\sin\theta - k \cos\theta)$.

There are many remarkable properties connected with the motion or equilibrium of bodies on inclined planes; but the preceding are those which are most fundamental and most frequently required.

INCLOSURE. The term inclosure is applied to the inclosing and partitioning of lands in England and Wales, which are comprehended under the general name of Commons or Common Lands. A knowledge of the present condition of the lands comprehended under this term enables us to form a better estimate of the state of agriculture in England and its capabilities of improvement. We thus learn also what was the general condition of the lands in England before inclosures were made.

It is necessary to define the terms Commons, and Commonable and Intermixed Lands. Commons or Common Lands are lands in a state of nature or waste, of which individuals have not the severalty. Commonable Lands are those lands which during a part of the year are in severalty, that is, occupied severally by individuals as their own, to the exclusion for the time of other people.

There is great variety in these commonable lands; but they may be divided into three classes, exclusive of wood-lands: First, there is open arable and meadow land which is held and occupied by individuals severally until the crop has been got in. After the crop has been removed, that is, during the autumn and winter, it becomes commonable to persons who have severalty rights in it, and they turn on to it their cattle without any limit, or without stint, as it is termed. Thus there is a divided use in these open lands: individuals have the exclusive right to the enjoyment of one or more of these strips of open land for a part of the year; and during another part of the year all these individuals enjoy this open land in common. Second, there is open arable and meadow land that is held in severalty during one part of the year, like the first class; but after the crop is removed, it is commonable not only to parties who have severalty rights, but to other classes of individuals: these lands are generally called Lammas Lands.

These commonable rights may belong to a particular class, as a body of freemen, or to all landholders. There is great variety in these two classes as to the severalty holdings also. "There are many cases in which the severalty holding varies year by year. There are in these open lands what is called a pane of land, in which there may be 40 or 60 different lots. It is reported to be a remnant of an old military custom, when on a certain day the best man of the parish appeared to take possession of any lot that he thought fit; if his right was called in question, he had to fight for it, and the survivor took the first lot, and so they went on through the parish. It often happens that in these shifting severalties the occupier of lot one this year goes round the whole of the several lots in rotation; the owner of lot one this year has lot two the next, and so on. When these lands are arable lands, they do not change annually, but periodically, according to the rotation of the crops. Then there is the old lot meadow, in which the owners draw lots for the choice. There are a great variety of circumstances under which the severalty ownership of these lands shifts from time to time—but after the severalty ownership has ceased, and after the crop has been removed, they all become commonable."

This is one among many instances of the existence of ancient usages in England, which are the same or nearly the same as the usages of nations that we call barbarous. Tacitus ('Germania,' c. 26) says of the ancient German mode of agriculture: "The lands, in proportion to the number of cultivators, are occupied by all in turns, which presently they divide among themselves according to their rank (merit). The extensive plains offer facilities for division. They change the cultivated fields yearly; and there is still a superfluity of land." The meaning of Tacitus is not clear. The following passage in Cæsar's account of the Gauls (vi. 22) is more distinct: "They pay no attention to agriculture, nor has any man a fixed quantity of land and boundaries of property: but the magistrates annually assign to the clans and tribes who have come together, as much land as they please and where they please, and in the next year they compel them to move to another spot." Herodotus (ii. 168) says that each member of the military caste in Egypt had a certain portion of land assigned to him; but they enjoyed the lands in a rotation, and the same persons did not continue in the enjoyment of the same lands. Strabo (p. 315) mentions a custom amongst the Dalmatians of making a division of their lands every eight years.

"The third class is that of grazing lands, where the rights of parties are settled and defined, the ordinary stinted pasture. The commonable lands are subject to very great variety and peculiarity; for instance, in some of these lands the right of grazing sheep at all belongs to a man called a flock-master, and he has the power, during certain months of the year, of turning his own sheep exclusively on all the lands of the parish; or, according to particular circumstances, his right is limited and restricted to turning sheep upon a certain portion of it, with a view to giving parties an opportunity of putting in a wheat crop. In those parishes where there is a flock-master who has a right of depasturing his sheep during a certain portion of the year over all the land of the parish, it is clear that no one can sow any wheat without having made a bargain with him for shutting up his own particular fields, or some portion of them."

"There is a very large extent of woodland in this kingdom that is commonable, strange to say, where certain individuals have a right during the whole year, to turn on stock, the owner of the wood having no means of preserving his property except by shutting out other commoners' stock by custom for some two or three years after felling. There is that right, as also the old right of estover, which is a very great inconvenience, namely, where parties have the right of cutting house-bote, and plough-bote, and fire-bote, and so on in woods belonging, *quâ* wood, to another party. There is a great deal of land subject to that ruinous custom. There are many varieties of these commonable lands, but these are the most prominent and remarkable of them."

Under such a system as this, it is obvious that these common fields must be ill cultivated. The intermixed lands cannot be treated according to the improved rules of good husbandry. It is stated that the simple re-distribution of intermixed lands, now held in parcels so inconvenient in form and size as to be incapable of good husbandry, would in many instances raise the fee-simple value of the lands from 15*s.* or 17*s.* an acre to 30*s.*

It was the opinion of witnesses examined before the parliamentary committee of 1844, on Commons' Inclosure, that judicious inclosure would make a large portion of common lands much more productive. Open arable lands are so intermixed that effectual drainage is nearly impossible. One witness said: "I have had occasion to go over two small properties, about 150 acres each; one I found in 301 different pieces, and another in a little more than a hundred. I mention this to show how the lands are frequently intermixed; they are therefore farmed at much greater expense; and it is impossible to drain them on the present improved mode of drainage, inasmuch as other parties are occupying the furrow by which the water should pass off." In the Midland counties, where there are these open arable fields, the course is two crops and a fallow, and every third year the flocks run over the whole field. The same witness considered that a fourth of all the arable land was totally unproductive. In cases where common arable fields have been subdivided and allotted, "the great improvement is, that in the first place every man has his allotment, and he deals with it as he pleases; he drains it, and crops it upon a proper course of cropping; he puts it in seed and keeps sheep upon it; he grows turnips and clover, or whatever he thinks proper." The same witness was of opinion that the average improvement in the value of common fields which had been inclosed was not less than 25 per cent. Indeed, the evidence that was produced before the committee established to a degree beyond what otherwise would be credible, the immense inconvenience and loss which arise from the system of intermixed lands, and their being also subject to commonage.

As to Common Rights, that is, rights of pasture and so forth on commons or waste lands, they are described generally under COMMON, RIGHTS OF. As to the common pasture lands, they also require an improved management. It is stated that commons are generally overstocked, partly in consequence of persons turning out more stock than they have a right to do, and partly by persons putting their stock on the common who have no right. In consequence of commons being overstocked, they are profitable to nobody; and a rule for regulating the quantity of stock would therefore be beneficial to all persons who are entitled to this right of common. Violent disputes also frequently arise in consequence of the rights of parties to commonage not being well defined. It is the opinion of competent judges that very great advantage would result from stinting those parts of commons that are not worth inclosure; and that "it would be in many instances highly desirable to inclose portions of a common for the purpose of cultivation, and to allot such portions of it, whilst it would be impolitic to do more than stint other portions of it." A *stint* may be defined to be "the right of pasturage for one animal, or for a certain number of animals, according to age, size, and capability of eating." The commons in fact are not now stinted by the levant and couchant right, a right which cannot be brought into practical operation; and besides this there are many commons in gross. [COMMON, RIGHTS OF.]

In 1836 an act (6 & 7 Wm. IV. c. 115) was passed for facilitating the inclosure of open and arable fields in England and Wales. The preamble to the act is as follows:—"Whereas there are in many parishes, townships, and places in England and Wales, divers open and common arable, meadow, and pasture lands and fields, and the lands of the several proprietors of the same are frequently very much intermixed and dispersed, and it would tend to the improved cultivation and occupation of all the aforesaid lands, &c., and be otherwise advantageous to the proprietors thereof, and persons interested therein, if they were enabled by a general law to divide and inclose the same," &c. Inclosures have been made under the provisions of this act, but the powers which it gives are limited, for the "act applies solely to lands held in severalty during some proportion of the year, with this exception, that slips and balks intervening between the cultivated lands may be inclosed." The lands which cannot be inclosed under the provisions of this act are "the uncultivated lands, the lands in a state of nature, intervening between these cultivated lands, beyond those that are fairly to be considered as slips and balks." However, it was stated in evidence before the committee of the House of Commons in 1844, that a large extent of common and waste land had been illegally inclosed under the provisions of the act, and the persons who hold such lands have no legal title, and can only obtain one by lapse of time. The chief motive to this dealing with commons appears to have been, that they thus got the inclosure done cheaper than by applying to Parliament for a private act.

In 1844 a select committee of the House of Commons was appointed "to inquire into the expediency of facilitating the inclosure and improvement of commons and lands held in common, the exchange of lands and the division of intermixed lands, and into the best means of providing for the same, and to report their opinion to the House." The committee made their report in favour of a general inclosure act, after receiving a large amount of evidence from persons who were well acquainted with the subject. The extracts that have been given in this article are from the printed evidence that was taken before the select committee.

In pursuance of the recommendation of the committee, an Act of Parliament was passed in 1845 (8 & 9 Vict. c. 118), the object of which is thus stated in the preamble: "Whereas it is expedient to facilitate the inclosure and improvement of commons and other lands now subject to the rights of property which obstruct cultivation and the productive employment of labour, and to facilitate such exchanges of lands, and such divisions of lands intermixed or divided into inconvenient parcels, as may be beneficial to the respective owners; and it is also expedient to provide remedies for the defective or incomplete execution and for the non-execution of powers created by general and local acts of inclosure, and to authorise the renewal of such powers in certain cases," &c.

It is not within the scope of this article to attempt to give any account of the provisions contained in the 160 sections of this act; but a few provisions will be noticed that are important in an economical and political point of view.

The 11th section contains a comprehensive description of lands which may be inclosed under the act, in which the New Forest and the Forest of Dean were excepted, but even with these portions have been since inclosed, and the new plantations are fenced for a certain time. The 14th section provides that no lands situated within fifteen miles of the city of London, or within certain distances of other towns, which distances vary according to the population, shall be subject to be inclosed under the provisions of this act without the previous authority of parliament in each particular case. The 15th section provides against inclosing town greens or village greens, and contains other regulations as to them. The 30th section provides that an allotment for the purposes of exercise and recreation for the inhabitants of a neighbourhood may be required by the commissioners under the act, as one of the terms and conditions of an inclosure of such lands as are mentioned in § 30.

The 108th section makes regulations as to "the allotment which upon any inclosure under this act shall be made for the labouring poor," and (sect. 109) "the allotment wardens (appointed by sect. 108) shall from time to time let the allotments under their management in gardens not exceeding a quarter of an acre each, to such poor inhabitants of the parish for one year, or from year to year, at such rents payable at such times and on such terms and conditions not inconsistent with the provisions of this act, as they shall think fit." Section 112 provides for the application of the rents of allotments; the residue of which, if any, after the payments mentioned in this section have been defrayed, is to be paid to the overseers of the poor in aid of the poor-rates of the parish.

Sections (147, 148) provide for the exchanges of lands not subject to be included under this act, or subject to be inclosed, as to which no proceedings for an inclosure shall be pending, and for the division of intermixed lands under the same circumstances.

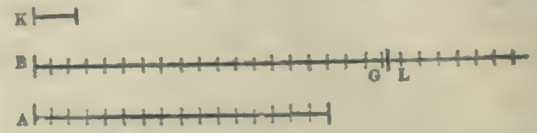
Under section 152 commissioners are empowered to remedy defects and omissions in awards under any local act of inclosure, or under the 6 & 7 Will. IV. c. 115; and under section 157, the commissioners may confirm awards or agreements made under the supposed authority of 6 & 7 Will. IV. c. 115, if the lands which have been illegally inclosed or apportioned or allotted, shall be within the definition of lands subject to be inclosed under this act. In accordance with this act two commissioners, with a secretary, were appointed, under whose management its provisions have been extensively carried into operation. The commissioners make yearly reports to parliament of the proceedings which have taken place, and one or more acts are passed every year confirming the inclosures submitted by the commissioners for approval. In their 13th annual report, presented in 1858, the commissioners state that the number of applications of all kinds for inclosures since the passing of the acts had been 2351, and that the whole acreage of inclosures confirmed prior to this report was 226,010 acres, while the acreage of inclosures in progress amounted to 262,418 acres.

The provisions of this act seem to be well adapted to remedy the evils that were stated in the evidence before the select committee; and there can be no doubt that agriculture has been greatly improved, the productiveness of the land increased, and employment given to labour by this judicious and important act of legislation.

INCOMMENSURABLE, INCOMMENSURABLES, THEORY OF. The application of arithmetic to any science of concrete magnitude supposes a certain magnitude to be taken as unity, and all other magnitudes to be expressed by the number of times or parts of times which they contain this unit. Such an application, therefore, made in the usual manner, requires the assumption of this proposition, that all magnitudes are either fractions or multiples, or compounded of fractions and multiples, of any magnitude that may be named. This proposition is not true; for instance, we shall presently prove that if the side of a square be called 1, no number or fraction whatsoever will exactly represent the diagonal. But we shall also prove that it may be made as nearly true as we please: for instance, that we may find a line as nearly equal to the diagonal as we please, which shall be a definite arithmetical fraction of the side. Quantities which are so related that when one is capable of being represented in terms of a certain unit the other is not, are called *incommensurables*. The reason is as follows: any two whole numbers or fractions of the same unit must have a common measure; thus, all whole numbers have the common measure 1; and any two fractions, $\frac{a}{b}$ and $\frac{p}{q}$ (a, b, p, and q being whole numbers), have the common measure $\frac{1}{bq}$, which is contained exactly aq times in the first, and bp times in the second. Conversely, any two magnitudes which have a common measure can be arithmetically represented by the same unit: for if A and B have the common measure M, and if this measure be contained 7 times in A and 10 times in B, then it is evident that by taking M as the unit, A is represented by 7 and B by 10. If, then, there be two magnitudes which cannot be represented by means of the same unit, they cannot have any common measure whatsoever, and are therefore *incommensurable*. It also follows from the preceding, that any two commensurable magnitudes must be to one another in the proportion of some one whole number to some other whole number.

To prove that there are such things as incommensurable magnitudes, we shall take the 117th (and last) proposition of the tenth book of Euclid, which demonstrates that the diagonal and the side of a square are incommensurable. Let D be the diagonal and S the side, and if they be not incommensurable let a and x be the whole numbers to which they are proportional; that is, let M be a common measure, and let D and S severally contain M, a and x times. Then the square on D will contain the square on M aa times; and the square on S will contain the square on M xx times. But the square on D is double of the square on S: therefore aa is twice xx. Now, let a and x have no whole common measure except unity, which may be supposed, for if they have a common measure, we may divide both by it, which will give two whole numbers in the same proportion, and so on until no common measure is left. Then, because a times a is double of x times x, a times a is an even number; whence a is an even number, for if a were odd, a times a would be odd. Therefore, x is not an even number, for if it were, a and x would have the common measure 2; whence x is an odd number. Let k be the half of a, which is a whole number, since a is even; whence $a = 2k$, and $aa = 4kk$, which is also $2xx$, and thence it follows that $xx = 2kk$. Therefore, xx is an even number, and x also; for if x were odd, xx would be odd: whence x is even. But it was just now proved to be odd; so that the same number is both odd and even, which is absurd. This contradiction follows whenever we suppose S and D to be in the proportion of any two whole numbers; consequently, S and D are not in the proportion of any two whole numbers, and therefore are incommensurable, for if they were commensurable they would be in the proportion of some two whole numbers.

We have next to prove that any two magnitudes whatsoever, being incommensurable, may be made commensurable by as small an alteration as we please in either.



Let A and B be two incommensurable magnitudes, and let K be a third magnitude of the same kind, which may be as small as you please, provided only that it be given and known. [INDEFINITE.] Now, some aliquot part of A must be less than K; if not the hundredth, try the thousandth; if not the thousandth, try the millionth, and so on. Whatever K may be, it is possible to divide A into equal parts, each of which shall be less than K. Let M be such an aliquot part of A, and having divided A into its parts, set off parts equal to M along B. Then A and B being incommensurable, B will not contain M, the measure of A, an exact number of times, but will lie between two multiples of M, say BG and BL. From this it is obvious that B does not differ from either BG or BL by so much as GL, and therefore not by so much as K. But BG and BL are both commensurable with A, since all three are multiples of M. Here, then, are BG and BL, the first a little less than B, and the second a little greater, neither differing from B by so much as K, but both commensurable with A. Thus it is also evident that two whole numbers may be found which shall be as nearly as we please in the same ratio as two given incommensurable quantities.

The difficulty thus inherent in the application of arithmetic to concrete magnitude is not met with in practice, because no case can arise in which it is necessary to retain a magnitude so closely that no alteration, however small, can be permitted. But in exact reasoning, where any error, however small, is to be avoided, it is obvious that the arithmetic of commensurable magnitudes, and the arithmetic (if there be such a thing) of incommensurable magnitudes, must not be confounded. The difficulty was overcome by Euclid, in the manner pointed out in the article PROPORTION, so completely and effectually that nothing has been added to his solution of it except unsuccessful attempts to evade it. Those who avoid the fifth book of Euclid generally substitute either the tacit assumption that all magnitudes are commensurable, which is not true, or some play upon words, which a person who feels the rigour of Euclid places on the same shelf with nature's horror of a vacuum and other explanations of the same kind. We could even point out a celebrated work on geometry which expressly rests on being able to make its errors too small to be perceived by the senses, and asks for no other reception of propositions which involve incommensurables.

The doctrine of incommensurable quantities was carried by Euclid to an extent which would excite as much admiration as any portion of his writings, if the tenth book were generally known and read as the production of a person unassisted by algebra. [IRRATIONAL QUANTITIES.]

INCOMPATIBLES, in Materia Medica, applied to those articles which are considered improper to be united in the same prescription. Strictly speaking, the term applies only to introducing into the same formula articles which exert a chemical action on each other, and so produce a result or compound of a useless or hurtful kind. Two or more articles may be introduced into a prescription, which by their combination neutralise the properties of each other. The resulting compound may be perfectly insoluble in the juices of the stomach, so as to be inert or hurtful by its insolubility. But this result is often sought on purpose to neutralise acrid or corrosive substances; such as when chalk or lime from a wall is given to a person who has swallowed oxalic acid. [ANTIDOTES.] But entire loss of power does not invariably result from combining substances which chemists deem incompatible; thus chalk and opium form a more powerful astringent than either singly given; and opium and acetate of lead in warm water form a fomentation of much use in erysipelas. But that utterly inert compounds often resulted from bringing together numerous ingredients is certain, as seen in the Polypharmacy of the ancients, of which the famous Mithridate is an instance. Even this has been surpassed in modern times, some prescriptions of Huxham containing above four hundred ingredients. On the opposite hand, excessive simplicity is perhaps too much aimed at in the present day. Dr. Paris' 'Pharmacologia' may be advantageously referred to; and Translation of the 'London Pharmacopœia,' by Richard Philips.

INCONCINNOUS INTERVALS, in Music, are sounds which agree with no scale, therefore are disagreeable to the ear, and never used in any kind of composition.

INCREMENT and DECREMENT. When two quantities are considered together, one of which is greater or less than the second, the latter is said to be the former with an increment or decrement. In the older English writings the calculus of differences is called the method of increments. This phraseology refers to the supposition of magnitudes being generated by continued increase or decrease as in the method of fluxions, so that two different magnitudes are spoken of as the same thing in different states, and of course at different times. Some difficulty to the beginner may be occasionally avoided by his stopping to interpret "let x become $x+h$" as follows: "let us, having considered the value of a function of x, proceed to consider the alteration which will arise if $x+h$ be written instead of x."

INCUBATION, ARTIFICIAL. [POULTRY.]

INCUMBENT. [BENEFICE.]

INDEFINITE means "not given or defined in magnitude." Thus, a definite straight line is that of which the extremities are known; an indefinite straight line (in length) is one of which the direction is given, and which may be supposed to have any length, or which can be lengthened if necessary, without contravening any of the conditions of the problem. Thus, Euclid, in the first book, constructs an equilateral triangle upon a definite straight line, and shows how to draw two lines making with one another the same angle as that made by two given indefinite straight lines.

There is, however, a reprehensible use of the word indefinite, which is found in many mathematical works; namely, the employment of it to avoid the odium which attaches to the word infinite. Thus we hear of making a magnitude indefinitely great, of an indefinitely small arc being equal to its chord, of the circle being a polygon of an indefinitely great number of sides. In all these cases it would be better, with a proper definition, to use the word infinite at once.

A want of proper distinction between definite and indefinite sometimes leads to confusion. For instance, it is said that if a straight line be halved, if its half be then halved, and if fresh portions be continually taken, each of which is the half of the preceding, the result will at last become less than "any line which can be named." This is not true if the line which is to be named be indefinite; that is, if we may at any part of the process make it as small as we please; for it is obvious that whatever a line may be, a smaller line can be named. But it is true of a definite line, made definite, or given in length, at the beginning of the process: name any line, however small, but such as you name let it remain; then, by continually halving any other line, however great, you must at last arrive at a line which is less than the length you named. The phraseology of a line "less than any line which can be named" has often caused a difficulty by not specifying the time at which it is to be named. The language used by Euclid himself is as follows (book x., prop. 1), and is free from the ambiguity in question: "Two unequal magnitudes being given, if from the greater be taken away its half, and from what is left its half, and if this be done continually, a magnitude will at last be found which is less than the lesser of the two given magnitudes."

INDELIBROME. [INDIGO.]

INDENTURE. [DEED.]

INDEPENDENTS, or CONGREGATIONALISTS, the name of a sect, class, or denomination of English Protestant Dissenters, one of the three who united form the Three Denominations, the other two being the Presbyterians and the Baptists.

When the principle of resistance to the power which maintained at least an outward and specious uniformity of Christian practice and opinion had received encouragement and was successful, it was not to be expected that nations who recognised that principle would agree among themselves respecting what should be done in their new condition of religious freedom. In England the politicians of the time soon succeeded in establishing a national church with pastors and bishops, and the church has been maintained in that form and order from the time of the Reformation, with the slight exception of the period of the Commonwealth. But there were many people in England who objected to several things which made a part of the constitution of that church; and as their objections consisted very much in the desire of what they considered a greater degree of purity in its forms, they were called in derision Puritans and Precisians, in which allusion was also included to the greater strictness with which they observed their religious duties, and their supposed peculiar preciseness in respect at once to an exactness of conformity to scripture precedent and to the obligations of a severe morality.

These persons were not all of one mind within themselves. Many uniting with these distinguishing characteristics the principle that, there being no scriptural authority for the Episcopal order, the government of the church or the superintendence of its ministers ought to be vested not in an individual, but in synods and presbyteries; these formed the Presbyterians. There were others who would have no union or government of the church, who regarded each congregation of faithful men as being in itself a church, and when properly constituted with deacons and a pastor forming a body which was independent of every other, and competent to its own direction and government without any interference from presbyteries, bishops, or from the state itself; this is the pure principle of English Independency.

Robert Brown, a clergyman of the reign of Elizabeth, is generally reputed to be the first person in England who publicly avowed this opinion, and acted upon it by the establishment of various such separate churches, which however had no enduring existence. There is some question whether he retained his opinions to the last: but it is certain that after he had given no small trouble to the authorities in the church, he was presented to the living of Achurch in Northamptonshire. He closed a long and very troubled life in the jail at Northampton, or very soon after he had left it, in 1630. [BROWN, ROBERT, in BIOG. DIV.]

Other persons, and some of them of celebrity in the history of the Puritans, adopted the opinion, but were restrained from acting upon it by the laws then in force for maintaining the Church of England as then established. But when Episcopacy was abolished and Monarchy had been overcome, there was a large party of these Independents which suddenly presented itself, who had a great share in the struggle then being made, and who were the means of preventing the establishment of a Presbyterian church in England, which it was the object of by far the larger portion of the Puritan body taking part in the contest to form. Cromwell belonged to the Independents. Dr. John Owen, dean of Christ Church, who was also for a time vice-chancellor of the University of Oxford, is considered as the chief ornament of this denomination at the time (the Commonwealth) when it first became considerable. [OWEN, DR. JOHN, in BIOG. DIV.]

What the issue might have been of the struggle between the principle of Independency and the principle of Presbyterianism cannot now be told, the king being soon restored, and with him the Episcopal church. In 1662 the Act of Uniformity was passed, the object of it being to exclude from the ministerial office in the Church of England divines of either of those opinions. The act required a direct acknowledgment of the principle of Episcopacy. The effect of it was, that about 1900 ministers retired from the places they held in the church. Some make them 2000. These are the ministers whom Dissenters mean when they speak of "the illustrious two thousand," "the ejected ministers," or "the Bartholomew worthies." During the reign of Charles II. every effort was made to prevent these persons continuing to exercise their ministry. But it was all in vain. They, or at least the greater part of them, persisted in preaching, notwithstanding the certain penalties of imprisonment and fine. However, the Revolution of 1688 freed them from these penalties; one of the first acts of the new government being to grant toleration to them, that is, to allow them to open meeting-houses, or chapels, and to conduct the services under the protection of the law.

The Independents were inconsiderable at that time as compared with the Presbyterians. Both however (and the Baptists also) built chapels for themselves and formed themselves into congregations, called the Presbyterian congregations and the Independent congregations; and each denomination had its own board or fund.

The 'Act of Toleration' was passed in 1689, and for the seventy years succeeding that date the Independent denomination dwindled (as indeed did the whole body of Dissenters), and it was in a very low condition when the state of things arose which we have now to describe.

About the middle of the 18th century there was an extraordinary revival of religious zeal under the influence created especially by the Wesleys and Whitefield. The Dissenters, like the Church, had adopted pretty generally the principle that to inculcate the moral duties, to present the paternal government of God as a source of consolation and of hope, to hold out the prospect of future accountableness and of eternal life, to show the evidence on which we receive Jesus Christ as the minister and messenger of his heavenly Father, were the principal subjects on which it was the duty of Christian ministers to insist. This it was easy to represent as an abandonment of the distinctive truths, as they are sometimes regarded, of Christianity; and many persons, under the preaching above alluded to, were disposed so to regard it, and to seek a ministry by whom these distinctive truths would be made more prominent. Most of these persons joined themselves to the Wesleyan Methodists, or to the Whitefieldian Methodists (since better known as the Countess of Huntingdon's Connexion); but there were many who declined to unite themselves with any of these bodies, and formed themselves into separate churches upon the Independent principle. These new societies incorporating with themselves the small remains of the old Independents of England,—who, in some instances had, throughout the period by some called the period of Religious Indifference, adhered to the original opinions of the Puritan body at large, which were Calvinistic, and had continued to make those opinions prominent in the public services,—or joining themselves to such decayed and decaying churches, gradually increased in numbers and influence, and constitute at the present day the large body of Dissenters called Independents or Congregationalists.

From the accession of George I., in 1714, when the London dissenting ministers of the three denominations (Presbyterian, Independent, and Baptist) presented an address to the king [WILLIAMS, DANIEL, D.D., in BIOG. DIV.], the three bodies have been accustomed to act together, by their appointed deputies, in reference to great public questions. Most of the old Presbyterian denomination in England having in the course of time adopted Unitarian sentiments, their representatives at length withdrew from the board. The distinctive appellation of "The Three Denominations" is however still kept up, the place of the retiring Presbyterians being occupied by representatives of those Presbyterians in England who hold the views of the Presbyterian churches of Scotland.

The Congregationalists have numerous chapels in London and in various parts of the country. They have also several institutions for the education of their ministers. They still maintain the principle of Independency; are in general strongly opposed to a national establishment, whether Episcopal or Presbyterian; and in doctrine vary, from the high Calvinism of the Savoy Confession, which exhibits the doctrines held by the Independents of the time of the Commonwealth, to the most moderate form of orthodoxy.

The number of Independent ministers is about the same as the number of chapels. The following is a list of the colleges and academies which are exclusively confined to the education of ministers for the Congregationalist denomination. Some of them have valuable endowments; others depend upon annual subscriptions for their support:—

Western college, Plymouth, founded about 1752; number of students, 21.

Rotherham college, Masborough, Yorkshire, founded in 1756; number of students, 17.

Brecon college, founded in 1760; number of students, 25.

Cheshunt college, founded in 1768; number of students, 25.

Airedale college, near Bradford, Yorkshire, founded in 1784; number of students, 20.

Hackney seminary, Middlesex, founded in 1796; number of students, 13.

Lancashire college, founded in 1806; number of students, 20.

Spring Hill college, Moretey, Birmingham; founded in 1838; number of students, 21.

New college, St. John's-wood, London, founded in 1850, by the union of the Coward, Homerton, and Highbury colleges; number of students, 55.

Connected with the Independent body there are also the Board of Congregational Ministers of London and the vicinity; the Congregational Board of Education, which maintains at Homerton a Normal school for the training of day school teachers; the Congregational Library in Bloomfield Street, London; and other institutions of an educational character. The Congregational Union of England and Wales, and the Congregational Union of Scotland, are voluntary associations of ministers and members of the Independent churches, which hold assemblies or conferences yearly, or half yearly, as circumstances may require, for mutual consultation; but not claiming any ecclesiastical authority over their members or churches. The managers and missionaries of the London Missionary Society chiefly belong to the Independent denomination.

There are also a Theological Hall of Congregational Churches at Edinburgh, founded in 1811; with 13 students; and a Presbyterian college at Caermarthen, founded in 1719; with 23 students.

The foregoing statistics are taken from the 'Congregational Year Book,' for 1860; which also states that there are 1600 churches of this connexion in England, 636 in Wales, 147 in Scotland and the Channel Islands, and 208 in the colonies. The ministers and missionaries throughout the British empire are estimated at 2734. In the United States there are said to be 2369 Congregationalist churches, and 2408 ministers.

INDETERMINATE, a word which is mostly applied in mathematics, not to the character of a magnitude, but of a problem. A question is said to be indeterminate when it admits of an infinite number of solutions: if the number of solutions, few or many, be finite, the problem is sometimes, but rarely, called indeterminate. The word indeterminate is also applied to the co-efficients of an assumed form of expansion, and the investigation by which they are then found is called the "method of indeterminate co-efficients." But when thus used the word means nothing more than unknown, and the co-efficients are unknown or undetermined quantities. In the French mathematical writings, the word *indeterminé* should sometimes be translated by indeterminate, sometimes by arbitrary, and sometimes by undetermined or unknown.

INDEX OF REFRACTION. [Light; Refraction.]

INDEX EXPONENT. [Binomial Theorem; Power.]

INDIA, ARCHITECTURE OF. The architecture of India does not extend back to a very remote period. Not only are there no architectural remains of the aboriginal races of Hindustan, but none are known to exist which can be assigned to the Aryan occupants. The earliest known buildings are of Buddhist origin, and are now considered by the best authorities to belong to the 3rd century B.C. When Buddhism was replaced by Brahmanism as the dominant form of religion, architecture underwent a considerable change; and it was again greatly modified by the Mohammedan invasion: but the original Buddhistic type or character was never wholly lost. Minor varieties and local modifications might easily be pointed out, but it will suffice for a broad view of the architecture of India to regard it as Buddhistic, Brahmanic, and Mohammedan.

In looking at the architecture of India most inquirers have been struck with its obvious affinity to that of Egypt; and perhaps a comparison of some of the resemblances and distinctions existing between Egyptian and Indian architecture, will facilitate our explanation of the latter. In the article on Egyptian Architecture we referred rather to points of difference and contrast between that style and the Grecian, than to anything of positive similitude, they being separated from each other by an exceedingly wide interval as to all that regards feeling and taste. The Egyptian and Indian styles, on the contrary, seem to come in contact with each other, agreeing most in those points wherein they most differ from Grecian and from modern taste. If there existed no other resemblance between the architecture of the two regions, there would be a decidedly strong one in their hypogea, or subterraneous cavern-structures hewn out of solid rock, works therefore more properly of exstruction than of construction, and to which, no doubt, ought to be ascribed the chief peculiarities of the styles originating in them, namely, extraordinary massiveness of bulk and proportions coupled with no less singular capriciousness of form. Where the forms are produced by cutting away instead of putting together and building up, they may be shaped quite arbitrarily, moulded according to fancy alone, because they still belong to one naturally coherent mass: whereas were the same forms worked out of separate pieces of material, not only would they frequently be at variance with security and stability, but they would occasion an enormous waste both of material and labour; the difference between the process of exstruction and that of construction being, that in the former the solids are only left after the operation of taking away, while in the latter they are produced by what is built up. This, in our opinion, goes far towards accounting for the various capricious, not to say unmeaning shapes we meet with in many of the columns of the cavern-temples of India; and these again, account for the similar taste which was manifested in later works of construction, a taste so remote from our own that the two can hardly be said to have any sympathies in common.

But in looking at even these rock-caves in detail, we find marked distinctions as well as broad resemblances. Thus while the shafts of the supporting columns have in the Egyptian examples no pedestals, and scarcely anything amounting to a distinct base,—and however much the column itself may be ornamented, the capital is plainly distinguishable from the other parts,—in the Indian cave-temples the columns often appear composed of fragments capriciously put together, it being nearly impossible to determine where their pedestals terminate and their shafts commence, or how much of these latter belong to the capitals. Another circumstance to be noticed, as in this instance constituting a striking point of difference from the practice of the Egyptians, is, that the columns are placed so far apart, and so stragglingly, as to resemble only occasional props, instead of a continued colonnade. In this respect however there appears to have been no fixed system, for in other examples the columns are placed so close together that parts of their capitals almost touch. Again the Indian cave-temples present a marked difference from those of the Egyptians in making in many of them an approximation to a regular vaulted ceiling, while the Egyptian edifices are all covered with flat horizontal ceilings. On the other hand, the affinity between the architectural taste of the two people is strongly marked by the prevalent use we observe, in the edifices of both, of colossal statues placed against piers or walls, sometimes quite attached to or sculptured on them; and which may therefore be considered quite as much to constitute part of the general embellishment, as to be specific objects of worship. In both too we find frequent use of Caryatid figures, or such as serve as columns; and either entire figures or the upper parts of them, both human and animal, enter abundantly into the composition of Indian columns and capitals: in this latter respect, however, as in some others, the architecture of India has more resemblance to that of Assyria than even to that of Egypt. A strong similarity also observable in the general disposition of the sacred buildings of the Indians and Egyptians is, that the former, like the latter, have generally an open or unroofed court before them (sometimes formed by clearing away the rock itself), leading to a vestibule, nave, and sanctuary, progressively diminishing in size. Neither is it uncommon in the excavated temples to meet with a series of small chambers along their sides, increasing their otherwise strong similarity of plan to those of Egypt. The profusion of inscriptions and symbolic sculptures on the walls affords also another characteristic point of resemblance.

Again in looking at constructive works, or edifices erected above ground, we can hardly avoid being struck by the prevalence of pyramidal masses and forms, as exhibited in pagodas, or towers, however great may be the difference in all except the general forms. One broad distinction however is, that, however highly enriched many Egyptian buildings may be, the mode of decoration employed in them is not of a kind to interrupt the simplicity of the outline, it being almost entirely *superficial*, that is, merely enriching surfaces, as a pattern wrought upon them would do; whereas the Hindus seem frequently to have affected the extreme both of massiveness and lightness in the same design, attaching very slender and merely ornamental pillars to enormous piers, which are the real supports.

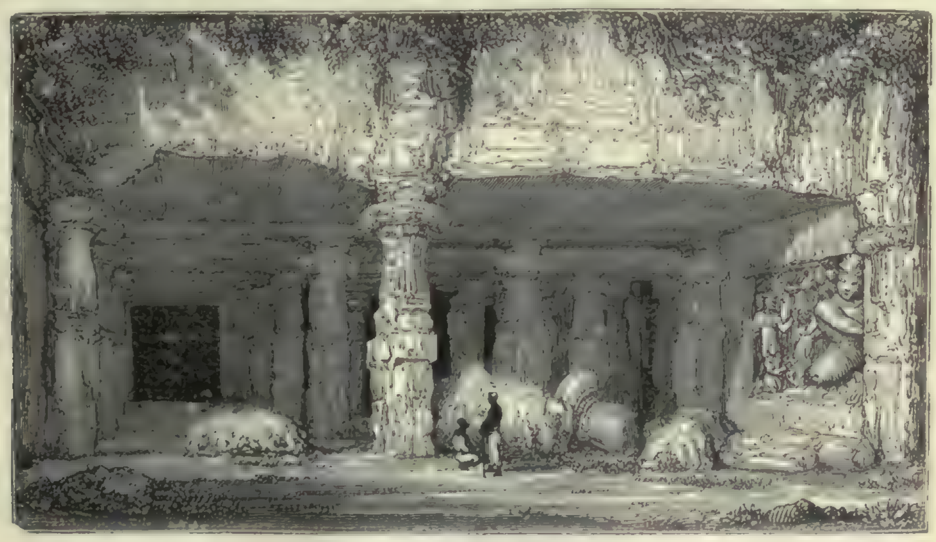
Buddhist Architecture.—Of constructed Buddhist temples proper there are unfortunately no examples left. Topes or relique-houses, some of them of large size, are indeed frequent: but the only true Buddhist temples remaining in India are those excavated out of the solid rock. These subterraneous edifices, combining often, like our own mediæval cathedrals and monastic establishments, a temple with an establishment for the attendant ecclesiastics, occur in surprising numbers, and, considering their age and the fact of their having belonged to a persecuted faith, they are in a remarkable state of preservation. They occur, not only singly, but in groups of from ten to a hundred distinct excavations, and there are in all perhaps not less than fifty of these groups in various parts of India: nine-tenths of those now known being found, according to Mr. Fergusson, within the limits of the Bombay presidency. The oldest are considered to be those of Behar and Cuttack; among the most remarkable are those on the Island of Elephanta near Bombay, at Kennareh, in that of Salsette; those at Ellora near Dowletabad; at Perwatam on the Kistna; those near the pass of Ajanti, and those at Carli, about 30 miles north-west of Poonah. Many of these excavations are of great extent, being composed of a series of apartments and recesses cut out of the rock. Merely as monuments of human labour and perseverance the works of this class would be astonishing, but it is their stupendousness combined with magnificence, barbaric and frequently monstrous, that imparts to them a character almost sublime. As if to imitate nature in her most minute as well as her grandest productions, while colossal statues and sculptures display themselves within these cavern-temples and on their walls, elaborate embellishments of detail are frequently given to the columns, which, as we have said, appear composed of fragments capriciously put together; what is sometimes described as a pedestal supporting the column, might with as much propriety be termed its lower portion, although square or polygonal, while the rest of the shaft is circular.

The rock-temple of Carli, one of the largest and most complete, and one of the oldest of these excavations, will serve to give a notion of their general form and character: we borrow our account of it from Mr. Fergusson, who has personally examined and described it, and indeed all the rock-temples of India; and whose exact as well as extensive knowledge of European as well as Asiatic architecture, renders his descriptions of especial value. In plan it is much like an early Christian church or basilica, "consisting of a nave and side aisles, and terminating in an apse round which the aisle is carried. The general dimensions of the interior are 126 feet, from the entrance to the back wall, by 45 feet 7 inches in width, from wall to wall. The side aisles, however, are very much narrower than in Christian churches, the central one being 25 feet 7 inches, so that the others are only 10 feet wide, including the thickness of the pillars. As a scale for comparison, it may be mentioned that its arrangements and dimensions are very similar to those of the choir of Norwich cathedral, or of the Abbey-aux-Hommes at Caen, omitting the outer aisles in the latter buildings. The thickness of the piers at Norwich and Caen nearly corresponds with the breadth of the aisles in the Indian temple. In height, however, Carli is very inferior, being only 42 or perhaps 45 feet from the floor to the apex, as nearly as can be ascertained.

"Fifteen pillars on each side separate the nave from the aisles; each of these has a tall base, an octagonal shaft, and richly ornamented capital, on which kneel two elephants, each bearing two figures, generally a man and a woman, but sometimes two females, all very much better executed than such ornaments usually are. The seven pillars behind the altar are plain octagonal piers, without either base or capital, and the four under the entrance gallery differ considerably from those at the sides. These sculptures on the capitals supply the place usually occupied by frieze and cornice in Grecian architecture; and in other examples plain painted surfaces occupy the same space. Above this springs the roof, semicircular in general section but somewhat stilted at the sides, so as to make its height greater than the semi-diameter. It is ornamented even at this day by a series of wooden ribs, probably coeval with the excavation, which prove beyond the shadow of a doubt that the roof is not a copy of a masonry arch, but of some sort of timber construction which we cannot now very well understand."

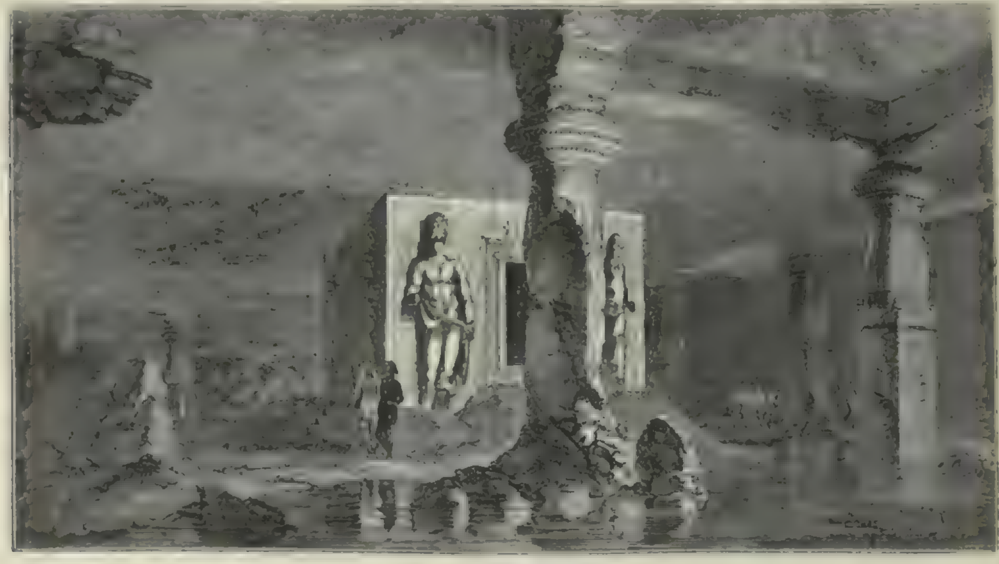
The shrine of the deity, a plain cupola on a circular drum, stands "immediately under the semi-dome of the apse, and nearly where the altar stands in Christian churches." At the opposite end under a gallery is the entrance, consisting of a central door, and one on each side leading into the aisles. Above the gallery the hall is entirely open, the opening looking like a great window with a horse-shoe arch; and through this window the whole of the light enters. A porch outside is seven feet wider than the body of the temple. It is closed in front by two thick octagonal pillars which support a plain mass of rock, but which Mr. Fergusson thinks was formerly ornamented by a wooden gallery, and surmounted by a dwarf colonnade or attic, and crowned with a cornice or some other ornament. In front of the porch stands the lât or lion-pillar (which appears always to have stood in front of the sacred buildings), which bears four seated lions, instead of the usual solitary animal. Of the effect of the exterior it is now difficult to form an adequate conception, but, says Mr. Fergusson, "the proportions of such parts as remain are so good, and the effect of the whole so pleasing, that there can be little hesitation in ascribing to such a design a tolerably high rank among architectural compositions. Of the interior we can judge perfectly, and it certainly is as solemn and grand as any interior can well be, and the mode of lighting the most perfect—one undivided volume of light coming through a single opening overhead at a very favourable angle, and falling directly on the altar or principal object in the building, leaving the rest in comparative obscurity. The effect is considerably heightened by the closely set and thick columns that divide the three aisles from one another, as they suffice to prevent the boundary walls from ever being seen, and, as there are no openings in the walls, the view between the pillars is practically unlimited."

The better known rock temple of Elephanta, or Goripura (the Mountain city), as it is called by the natives, is of later date and larger dimensions. It is magnificently situated, being excavated about half way up the side of a mountain, and in the midst of scenery of more than ordinary grandeur. The entrance, which is hewn out of a stone resembling porphyry, is by a spacious front, which is supported by two massive pillars (one of which has fallen), and two pilasters, forming three openings, under a thick and steep rock overhung by brushwood and wild shrubs. "The whole excavation consists of three principal parts: the great temple itself, which is in the centre, and two smaller chapels, one on each side of the great temple. These two chapels do not come forward into a straight line with the front of the chief temple, are not perceived on approaching the temple, and are considerably in recess, being approached by two narrow passes in the hill, one on each side of the grand entrance, but at some distance from it. After advancing to some distance up these confined passes, we find each of them conduct to another front of the grand excavation, exactly like the principal front which is first seen; all the three fronts being hollowed out of the solid rock, and each consisting of two huge pillars with two pilasters. The two side fronts are precisely opposite to each other on the east and west, the grand entrance facing the north. The two wings of the temple are at the upper end of these passages, and are close by the grand excavation, but have no covered passage to connect them with it." (Erskine.)



Entrance to the Temple at Elephanta.

"From the northern entrance to the extremity of this cave is about 130 feet, and from the east to the west side 133 feet. Twenty-six pillars, of which 8 are broken, and 16 pilasters, support the roof. Neither the floor nor the roof is in the same plane, and consequently the height varies, being in some parts 17½ feet, in others 15 feet. Two rows of pillars run parallel to one another from the northern entrance, and at right angles to it, to the extremity of the cave; and the pilasters, one of which we have described as standing on each side of the two front pillars, are followed by other pilasters and pillars also, forming, on each side of the two rows already described, another row running parallel to them up to the southern extremity of the cave. The pillars on the east and west front, which have been described as like those on the north side, are also continued across the temple from east to west. Thus the ranges of pillars form a number of parallel lines intersecting one another at right angles, the pillars of the central parts being considered as common to the two sets of intersecting lines. The pillars vary both in their size and decorations, though the difference is not sufficient to strike the eye at first. Each column stands upon a square pedestal and is fluted, but instead of being cylindrical is gradually enlarged towards the middle. The capitals exhibit that bulbous form which is one of the most distinctive characteristics of Indian architecture. Above the tops of the columns a kind of ridge has been cut to resemble a beam about 12 inches square, and this is richly carved. Along the sides of the temple are cut between 40 and 50 colossal figures, varying in height from 12 to 15 feet; none of them are entirely detached from the wall. Some of these figures have on their heads a kind of helmet; others wear crowns with rich devices; and others, again, are without any other covering than curled or flowing hair. Some of them have four and others six hands, holding sceptres, shields, symbols of justice, ensigns of religion, weapons of war, and trophies of peace. On the south side, facing the main entrance, is an enormous bust with three faces; of which the central face measures 5 feet in length; the width from the ear to the middle of the nose is 3 feet 4 inches; the breadth of the whole figure is near 20 feet. To the left of this bust, amid a group of uncouth figures, is one (a female figure with four arms) to which Niebuhr has given the name of Amazon, from the fact of its being without the right breast. At the west side of the temple is a recess, 20 feet square, having in the centre an altar, upon which are placed symbols of the worship once practised here. The entrance to this recess is guarded by eight naked figures, each 13½ feet high, sculptured in a manner which shows that the people by whom they were executed must have made considerable progress in the statuary's art. The cave is not at present used as a temple, nor has it any establishment of priests connected with it, although it is frequently visited by devotees for the purpose of offering prayers and oblations.



Temple of Elephanta.

The roof of the temple at Elephanta is flat; in others it is hollowed out so as to resemble more or less a regular vaulting. Of this last-mentioned kind is the temple of Kennarch, or Canarah, in Salsette, which is exactly on the same plan as that at Carli, and the principal object or idol is alike in both, consisting, as Moor describes it, "of a vast hemisphere of stone resting on a round pedestal of greater diameter having its convexity surrounded by a sort of canopy or umbrella of peculiar construction." The ground-plan of an arched temple of Buddha at Ellora is exactly similar, but there is here a figure of Buddha himself in front of the cylindrical pedestal and characteristic umbrella ornament just mentioned. The temple at Salsette Mr. Fergusson is inclined to reckon among the latest of the Buddhist edifices of this class, regarding it as a copy of the temple at Carli, and as late in date as the 9th or 10th century of the Christian era.

The Buddhist rock-cut monasteries are much less rich in detail than the temples. They consist of a central hall, around which are numerous plain cells for the priests of various grades. There were places for private devotion; the public worship and more imposing ceremonies were performed in the temples. The oldest of these caves occur at Behar, in the Bengal presidency, but they are quite unornamented. At Cuttack is one known as the Tiger Cave, from the exterior being carved into the form of a tiger's head, the entrance being through the animal's open mouth. Another in the same neighbourhood is distinguished by being two stories in height, and having a verandah carved along the whole extent of its front. Dr. Impey has published a full account of a series of Buddhistic caves at Koolvee, in Central India, which are "cut literally round the circumference" of a hill, and are in all about fifty in number. Among them are six dagobas (or relic-chambers), connected with each of which is a *shala*, or hall of assembly, and a larger cell for a superior priest. Two only of the caves are supported by pillars, and these are each 32 feet by 24 feet. "One of these caves is subordinate to a dagoba, which stands in a court-yard in front of it, flanked by an erect colossal figure of Budh, in the attitude of expounding; and the other to a seated image of Budh, which is in a cell opposite the porch flanked on either side by diminutive dagobas in relief." The figures are of rude execution, and much defaced and weatherworn. The inferior cells are all small in size and quite simple in plan.

The walls of the larger chambers of some of these rock-monasteries are profusely decorated with paintings of religious and historical subjects, executed in fresco or distemper, portraits of Buddhs and Buddhist saints covering the pillars, and the roofs being at the same time painted with scrolls and other architectural designs. In many places these paintings have been destroyed by the effects of damp, or by the hand of man, but at the Ajunta and elsewhere they "remain nearly complete, and as fresh as the day they were painted. A competent artist, Capt. Gill, of the Company's Service, has been employed for some years in copying these." Their publication would doubtless, as Mr. Fergusson remarks, throw light not only on the "manners and customs of India more than a thousand years ago, but illustrate also to a considerable extent the form and ordinance of the buildings they adorn." Dr. Impey ('Journal of the Royal Asiatic Society,' Bombay Branch, July, 1856,) describes a series of historical and mythological paintings on the famous caves of Bágh in Rath, on the Nerbudda, which still extend above 220 feet in length. The paintings are in a double row, one set above the other, the figures being about the natural height. The designs are very varied, and display no little skill. "The surface extent of the work thus elaborately depicted must have been at least 3000 feet." They appear to be not later in date than the 5th century, A.D.

The other Buddhist religious edifices have been all classed under the general term *Topes*. They consist of detached pillars and towers, and of buildings, usually circular in form but always surmounted with a dome. The pillars are the oldest. All that remain in India proper are monoliths, but there appears to be little doubt that built pillars did formerly exist; and Mr. Fergusson, who adduces two such pillars as still standing among the topes of Cabul, thinks that their destruction is "sufficiently accounted for by the ease with which they could be thrown down and their materials removed, when they had lost the sanctity by which alone they had been protected." Of these monoliths, or lâts, the oldest known were erected by Asoka about 250 B.C., and bore inscribed on them the Buddhist creed. Three of them are still standing near the river in Tirhut, and are each surmounted by a seated lion. One which has been removed and set up on a pedestal at Allahabad, is 47 feet high, and the shaft is 3 feet in diameter at the base, diminishing to 2 feet 2 inches at the summit. It is noteworthy that "the necking immediately below the capital represents, with considerable purity, the honeysuckle ornament of the Assyrians." (Fergusson). They were most probably always erected in front of temples and sanctuaries, where some are still found.

The topes properly so called are spacious circular domical buildings, erected as reliquaries of Buddha or some of the more eminent Buddhist saints. They occur in groups near the Indus and the Ganges, at Behar and Tirhut, around Bhilsa in Central India, and in Affghanistan. These topes will be found fully described in the valuable works of Mr. Fergusson, and in the elaborate treatise of Major Alexander Cunningham, 'The Bhilsa Topes; or Buddhist Monuments of India,' 8vo. 1854. The oldest of these topes are little more than tumuli; later the hemispherical cupola was supported on a cylindrical basement; and eventually they assumed the character of a tower surmounted with a cupola. In size they vary from a few feet up to 150 or 200 feet in diameter. The great Sanchi Tope, near Bhilsa, the finest and most perfect in India, will serve as an example of this class of buildings. It is situated on the western side of a lofty hill, and is inclosed within a great court-yard which averages 150 yards in length, and is 100 yards broad. "The great tope itself is a solid dome of stone and brick, 106 feet in diameter and 42 feet in height, springing from a plinth of 14 feet, with a projection of 5½ feet from the base of the building, and a slope of 2½ feet. The plinth or basement formed a terrace for the perambulation of worshippers of the enshrined relic; for on the right pillar of the North Gateway there is a representation of a tope, and of two worshippers walking round it with garlands in their hands. The terrace was reached by a double flight of steps to the south, connected by a landing ten feet square. The apex of the dome was flattened into a terrace 34 feet in diameter, surrounded by a stone railing of that style so peculiar to Buddha monuments, that I will venture to call it the Buddhist Railing." This terrace formed the basis of the *tee* or capital (a square box-like ornament probably intended to serve as a relique-case or a symbol of one) with which these structures were always crowned. "The total height of the building, including the cupolas," continues Major Cunningham, "must have been upwards of 100 feet. The base of the tope is surrounded by a massive colonnade, 144½ feet in diameter from east to west, and 151½ from north to south." The entrance is by four gateways, each formed by two square pillars, 18 feet high, covered with carvings, and crowned with elephant capitals. These support three elaborately carved lintels slightly curved upwards in the centre, and terminating in Ionic scrolls and surmounted with emblems: in all the gateways are 33½ feet high. On all sides are ruined temples, fallen columns, and broken sculptures; while 30 or 40 smaller topes combine to form the group of which the great tope is the centre.

With respect to the character and arrangement of the topes, it will be enough to quote what Major Cunningham says of those of Bhojpur: "The topes occupy four distinct stages or platforms of the hill. The largest topes, six in number, occupy the *uppermost* stage, and were, I believe, dedicated to Buddha; that is, either to the celestial Buddha, *Adináth*, or to the relics of the mortal Buddha, *Sákya*. This view is borne out by the facts that the largest tope contained no deposit; and that the second and third sized Topes yielded crystal boxes, one of which, shaped like a tope, contained only a minute portion of human bone smaller than a pea! The second rate topes, sixteen in number, stand on the second stage. According to my view, these topes contain the ashes of those who had reached the rank of Bodhisatwa. We discovered relics in five of these topes, but there were no inscriptions of any historical value. The third stage of the hill is occupied by seven small topes, all of which I suppose to have been built over the remains of the third grade of Pratyeka Buddhas. Of the eight topes which stand on the lowest stage of the hill, one is much larger than any of those on the third stage. These topes were, I believe, built over the ashes of the lowest grade of the Buddha community, the Sráwaka Buddhas."

Very splendid examples of Buddhist temples, topes, and dagobas occur, at Anuradhapoora, the ancient capital, and in several other places in the island of Ceylon. These, from their having escaped the destructive hand of adverse religious bodies, serve to elucidate many interesting points in the history of Buddhist architecture which the remaining monuments of the peninsula leave in obscurity. Our space will not, however, allow us to notice them here: they will be found described in the works of Mr. Fergusson and Sir Emerson Tennent. In Burmah also occur numerous costly Buddhist edifices, some of them on a scale of great magnitude, as the great pagoda of Pegu—a comparatively modern structure—the diameter of whose base is 395 feet, while its height is 331 feet above the artificial terrace on which it stands. At Java again are several vast Buddhist temples, as that of Boro Buddor, which is a square nine-storied many-pinnacled pyramid, the base of which is 400 feet across. In style, however, these last are far more barbaric than the older buildings of Hindustan.

Based on the Buddhist style, but much more highly ornamented, are the temples erected by the Jainas, the great sect which sprang up at the decline of the Buddhists. [JAINAS.] Some of these temples are distinguished alike by chasteness, symmetry, and beauty of design, and by rich and exquisite finishing. That at Ajmeer, in Rajpootana, is remarkable for the elegance and slenderness of its columns, so very different in their character from those in the excavated works, and which seem therefore to indicate a totally different period of art. They are about forty in number, and partake somewhat of a candelabrum shape, although no two are exactly alike. The ceiling is highly enriched with square panels or coffers, containing others in the form of lozenges, enriched with foliage and sculpture, in style not very much unlike the *cinquecento* of the Italians. This temple is surrounded by a superb screen of Saracenic architecture, assigned by Tod to the first dynasty of the Ghorian Sultans. The same writer dwells upon the analogy observable between the details of the columns in this temple and the ornaments of Gothic buildings; and it would hardly be fanciful to designate Jaina architecture the Decorated Buddhist style. Some of the oldest and finest examples of the style are found about Mount Abu in Gujerat, but they occur over a wide space, though often altered, like the temple at Ajmeer, by Mohammedan additions. The temples appear always to include a sanctuary, lighted only from the door, and terminated upwards by a pyramidal spire-like roof. In this chamber is placed a seated figure of the saint to whom the temple is dedicated; and attached to it is a spacious portico, which is sometimes surmounted by a cupola. These porches are often extremely rich in ornamentation: that of the temple of Vimalah Sah at Abu (described and figured by Mr. Fergusson) has 48 elaborately carved columns; yet the exterior of the temple is perfectly plain. The Jainas were the first to erect hollow cupolas in India, those in the Buddhist topes being all solid. The cupolas of the Jaina temples are formed by placing the stones so as gradually to project one beyond the other, the apex being closed by a circular key-stone. The principle therefore is that of a horizontal or vertical instead of a radiating pressure, and the edges of all these projections being rounded off, the spectator sees, on looking up, a vault composed of gradually diminishing circles or annular courses of masonry. Brackets and struts are occasionally employed with great skill to assist in bearing the superstructures. According to Mr. Fergusson, some of these Jaina cupolas are "the most exquisite specimens of elaborate roofing that can anywhere be seen." Usually the octagonal cupolas are carried on eight thick pillars; but the base is always made square by the addition of four other pillars at the angles; while in smaller buildings two more are added on each face, making twenty in all. "Sometimes, however, the same system of aggregation is carried on till the number reaches fifty-six, which is the largest number I ever saw surrounding one dome; but any number of these domes may surround one temple, or central dome, and the number of pillars consequently be multiplied *ad infinitum*." (Fergusson.) The variety, picturesqueness, and splendour of effect, and the rich play of light and shade, thus produced, however impure the style of architecture may be in itself, can readily be imagined. Many of the most superb of the Jaina temples have been converted into Mohammedan mosques.

The Jainas appear to have also wrought out cave-temples; among others the Subba caves of Ellora have been attributed to them; but there is nothing in their works of this class sufficiently distinctive to call for a particular description.

Following their Buddhist predecessors, the Jainas showed a great partiality for erecting towers; and their towers, though less substantial, were little less rich than their temples. Few of them however are left now. Two of them still stand within the fort of Chittore. The older and smaller is of the 10th century, A.D.; the larger is of the 15th. This last is 30 feet wide at the base; 120 feet high; and is formed in nine stories, the whole being covered with architectural and sculptural ornament. The body, or shaft, of the tower is smaller than the base, but it swells out again towards the summit, which is surmounted with a small dome, and which was probably crowned with a tee. It is fully described and figured in Mr. Fergusson's 'Illustrations of Indian Architecture,' and 'Handbook of Architecture.' This class of dagoba is the immediate prototype of the Chinese nine-storied pagoda.

Brahman Architecture is best studied in the temples of Southern India. In Northern India the style is a good deal varied and less pure. What may be considered as the normal type of a Brahman temple consists of the *vimana*, a tower square in plan and pyramidal in form, built over the sanctuary or cell in which is the image or emblem of the god; a *mantapa*, or porch, placed before the principal entrance to the sanctuary; *gopuras*, or pyramidal gate towers, which serve as entrances to the enclosures in which the vimanas are placed; and a *choultrie*, or spacious pillared hall.

The Vimana, or inner temple, has a perpendicular base of granite or stone, which is always decorated with pilasters, niches, and other architectural ornaments. From this rises in distinct stages the pyramidal roof, usually constructed of brick and covered with stucco, and crowned with a small dome-like termination, evidently borrowed from the older Buddhist builders. The most splendid example of one of these buildings is the great temple at Tanjore, from the annexed representation of which their general character may be understood. The base of this temple is 82 feet each way, and the pyramidal roof rises in 14 stories to a height of about 200 feet.

The porch, or Mantapa, is in plan usually similar to the temple itself, has a door on each of the four sides, and a pyramidal roof, but much lower than the roof of the temple, unsupported by pillars, and without a crowning ornament. Placed against the door of the cella, the mantapa effectually excludes the light of day from the sacred chamber, which consequently is lighted only by lamps.

Temple at Tanjore.

The Gopuras, or gate-pyramids, which give entrance to the rectangular court which encloses the temple, are usually proportioned in size and number to the length of wall which surrounds the court. Some of these gateways are much larger than the temples to which they are appended, and the entire surface of many of them is covered with ornament. One at Combaconum is 12 stories high. In form they are similar to the vimanas, except that they are not so deep as they are wide, and they are always pierced with a doorway occupying from a fourth to a seventh of the whole width.

"By far the most extraordinary buildings connected with these fanes are the pillared colonnades or Choultries, which occupy the spaces between the various enclosures of the temples. They are of all shapes and sizes, from the little pavilion supported on four pillars up to the magnificent hall numbering a thousand. Their uses too are most various; in ancient times they served as porches to temples; sometimes as halls of ceremony, where the dancing girls attached to the seminary dance and sing; sometimes they are cloisters, surrounding the whole area of the temple; at others swinging porches, where the gods enjoy at stated seasons that intellectual amusement. But by far their most important application is when used as nuptial halls, in which the mystic union of the male and female divinities is celebrated once a year. Those dedicated to these festivals sometimes attain an extent of 1000 columns, and are called in consequence halls of 1000 columns, though they do not in all instances make up this complement." (Fergusson.) The pillars are in most instances composed of granite, and covered with sculpture from the base to the capital, every pillar being usually unlike the others in the details, though similar in general character and dimensions. The effect of many of these halls is very impressive.

As an example of the style of southern Hindustan we may refer to the small but very elegant temple at Bareilly, as a structure of most complicate and exquisite workmanship. Although placed within an area about 250 yards square, the body of the temple, or sanctuary (*mindra*), over which rises a pyramidal *sikr*, or roof, is only 21 feet square, but the addition of the domed vestibule (*munduf*) and the projecting portico composed of four superb columns makes the whole 44 feet by 21. The ceilings are elaborately worked, and that of the portico consists of a single block. Facing this temple is another splendid edifice, called the Séngár-chaori, or Nuptial Hall, a square of about 40 feet, with a double range of pillars on each side forming open colonnades. Its *sikr* is the frustum of a pyramid, each stone of which is elegantly carved, and gradually decreasing in size to the *kullus* or ball.

After the introduction of the Saracenic architecture by the Mohammedan invaders, the Hindu architects adopted in their secular buildings many of the features of the new style. Some of the palaces constructed under this foreign influence are extremely picturesque, as the palace of Madura, commenced in the early part of the 17th century. But the decline of Hindu architecture was thenceforth rapid; innovations of all kinds were introduced, and the native barbaric magnificence, originality, and piquancy were lost, without being replaced by western purity, simplicity, or taste.

The Mohammedans at first, it is evident, were led to imitate much both of the general forms and the details of the ecclesiastical architecture of the people they had conquered. But they brought with them the principle of the arch, and with it a different and more daring style of construction. They never wholly abandoned the forms they had adopted from the Hindus; but they so modified and applied them that ultimately their style became rather a variety of the true Saracenic or Moorish style than of either of the styles of India. Hodges, who has carefully studied the original buildings, indeed refers us to the mosque at Chunar Gur, on the Ganges, as a proof of the "perfect similarity of the architecture of India brought thither from Persia by the descendants of Timur, and that brought into Europe by the Moors of Spain." "All the minuter ornaments," he says, "are the same, the lozenge square filled with roses, the ornaments in the spandrels of the arches, the little panellings and their mouldings; so that a person would almost be led to think that artists had arrived from the same school, at the same time, to erect similar buildings in India and in Europe." This is, however, too strongly put, and is contradicted by the details of his own plates. There are, in truth, many features in the Mohammedan architecture of India which stamp it as distinct from the Moorish style of Europe. [SARACENIC ARCHITECTURE.] Among these are its numerous bulbous domes, which are frequently applied even to minarets, and the projecting galleries given to these latter, to which may be added the use of very projecting balconies, supported on massive cantilevers or consoles. One of the most splendid examples of this later style is the celebrated Taje Mahal, near Agra, erected by Shah Jehan as a mausoleum for his wife in the 17th century. "It stands," says Bishop Heber, "in a square area of about 40 English acres, enclosed by an embattled wall with octagonal towers at the angles, surmounted by open pavilions, and four very noble gateways of red granite, the principal one of which is inlaid with white marble, and has four high marble minarets. The space within is planted with trees and divided into green alleys leading to the principal building, which is a sort of solid pyramid surrounded entirely with cloisters, galleries, and domes, diminishing gradually till it ends in a square platform of white marble, surrounded by a most elaborate lattice-work of the same material, in the centre of which is a small altar-tomb, also of white marble, carved with astonishing delicacy and beauty." The cost of this tomb is said to have been 750,000*l*. An equally celebrated but inferior work of this class is the mausoleum of Hyder Ali at Seringapatam.

Next to the tombs, perhaps, as characteristic of Mohammedan architecture in India, are the mosques, some of which are of considerable magnitude and magnificence. In the gateways, which are made a striking feature, the Moorish arch inclosed within a square-headed panel is applied with excellent effect. In the mosques themselves there is often a great multiplicity of hemispherical or bulbous domes. The mosque at Mandu, the great mosque at Delhi, and the pearl mosque of Shah Jehan at Agra, are very beautiful examples of Mohammedan temples. Some of the minarets are highly enriched and of unusual dimensions; that of Kootub is 48 feet at the base and 242 feet high, though it has lost its capital—being only exceeded among Mohammedan buildings by the minaret of the mosque of Hassan in Cairo.

Still more splendid are, or were, the palaces, which are in some instances of prodigious extent, finished in a style of unbounded luxuriance, full of fanciful and admirably-executed ornamental details, and unquestionably picturesque in appearance. Among the most superb are those of Agra, Allahabad, Lucknow, and Delhi.

INDICATOR. The word *indicator* is used, generically, in mechanical engineering, to designate any contrivance by means of which it is possible to calculate the force exerted by the intervention of a machine; but it has of late years been almost exclusively applied to the instruments by which the pressure of steam in the cylinder of a steam-engine is registered throughout the whole of its duty, or by which the amount of vacuum or exhaustion attained by the use of the air-pump and condenser, is recorded. The indications of the pressure of steam in the boiler are marked by the *pressure gauge ;* the indications of the useful amount of power transmitted to the first motion-wheel are recorded by the *dynamometer ;* whilst the meaning of the generic term is limited to the sense above given. Different constructors have introduced varieties in the form and working details of their indicators; but they all are identical in principle. They are all self-registering, and show (by means of a curve traced on a slip of paper by a pencil attached to the part of the indicator immediately connected with the steam in the interior of the cylinder, or with the vacuum), the difference between the pressure of the atmosphere around the cylinder, and the pressure within the cylinder, at every part of the up and down stroke of the piston, for that end of the cylinder to which the indicator is attached. In order to effect this object, a small cylinder is connected with the larger one in which a steam and air tight piston works, and the rod of this piston passes into another small cylinder, in the interior of which is placed a spiral spring, which in its turn presses upon the rod of the indicator piston in such a manner as to keep the latter in the centre of its cylinder, when the pressure of the atmosphere and of the vapour in the cylinder of the engine balance one another. In proportion as the relative pressure increases on either side of the cylinder of the indicator, it will be found that the piston will rise or fall; for spiral springs (as Messrs. Hann and Gener observe), are extended and compressed through equal spaces by equal and opposite pressures. There is a stud passing from the top of the piston-rod through a slot in the spring cylinder, and an index pointer shows on a scale attached to the side of the slot the pressure acting upon the piston. The description and use of this instrument are well explained in Hann and Gener's book, above quoted, entitled 'The Steam Engine,' 1854, &c. &c.

INDICTION; CYCLE OF INDICTION. [PERIODS OF REVOLUTION.]

INDICTMENT is a written accusation of one or more persons of a crime or misdemeanour presented by a grand jury. The sheriff returns to every session of the peace and every commission of oyer and terminer and jail delivery at least twenty-four freeholders of the county, twelve of whom, at least, and not more than twenty-three, are sworn upon the grand jury. They are instructed in the articles of their inquiry by the judge, and then withdraw to sit and receive bills of accusation, which are presented to them in the name of the crown, but at the suit of any private person. The decision of the grand jury is not in the nature of a verdict as to the guilt of the accused, but merely the expression of their opinion that from the case made by the prosecutor the matter is fit to be presented to the common jury. In conducting the inquiry the evidence in support of the accusation only is heard. If the grand jury think the accusation groundless, they indorse on the bill "not a true bill," or "not found;" if the contrary, "a true bill;" and in finding a true bill twelve at least of the grand jury must concur, because no subject can be put to answer an accusation except such as is credited by such a number of his fellow-citizens. Anciently the words "ignoramus" and "billa vera" were used. When a bill is found to be a true bill, the trial of the accused takes place in the usual form; when the bill is "ignored," the accused is discharged, but a new bill may be preferred against him before the same or another grand jury. Sometimes, when the bill is ignored on account of some slip or error, the judge will direct the accused to be kept in custody, in order to prevent him from escaping from justice.

INDIGESTION. [DYSPEPSIA.]

INDIGO. This well known colouring matter is a product of the vegetable kingdom, being derived from the cellular tissue of the leaves of certain plants. For the names and habitats of these plants, see INDIGOFERA, in NAT. HIST. DIV.

Indigo was well known to the ancients. Bands of cloth, evidently dyed with this material, are met with in the wrappings of Egyptian mummies; and Dioscorides and Pliny mention it as an Indian product under the names of *ινδικον* and *indicum*. It began to be employed in Europe about the middle of the 16th century, but owing to the opposition of the cultivators of the native woad, its importation into England was prohibited; and it was not till the time of Charles II. that these prejudices were overcome. At the present time there are sent into this country from 60,000 to 70,000 cwts. of indigo per annum.

The cultivation of the indigo plants is extensively carried on in various parts of India and America. In the spring the seeds are sown, at the rate of about a dozen pounds per acre; the plants grow rapidly, commencing to blossom in three months time, when they are cropped and again allowed to grow till they are sufficiently mature to admit of another cutting. Occasionally a third and even a fourth cropping is made, but each of these contains successively less and less of the matter that yields the colouring principle.

The indigo plants present no appearance when growing that would lead an observer to suppose they contained any matter capable of producing colour; nor is it yet satisfactorily determined in what form the indigo pre exists in the vegetable tissues. From the recent experiments of Schunk ('Manchester Memoirs,' 1855, vol. xii., p. 177), it would seem that a principle, termed by him *Indican*, of yellow colour, and having the composition (C_5 H[illegible]NO_{36} ?), occurs naturally in the plants, and that it is from the decomposition of this body, under circumstances immediately to be described, that the indigo is produced.

The manufacture of indigo in the East Indies is conducted somewhat after the following plan. The recently cut plants are placed in large stone cisterns, called fermenting vats, or steepers, and covered with water; fermentation soon commences, large quantities of gas rise in bubbles to the surface, and the whole mass becomes covered with a copper-coloured scum. After about fifteen hours fermentation ceases, and the liquor is then run off into another vat placed on a lower level. Here it is brought well into contact with the air by beating with wooden paddles for about an hour and a half. During the beating the contents of the vessel darken in colour, and the indigo separates out in flocks; these are allowed to subside, heated to boiling to effect the removal of certain impurities, then collected on woollen strainers, and finally pressed, dried, and the mass cut up into blocks for sale. At some places the plants are, after cutting, spread out to dry in the sun, it being supposed that a better quality of indigo is thus obtained.

Indigo is usually met with in commerce under the form of cubical masses or cakes, which are brittle and of characteristic colour, a colour that ranges from a deep blue containing a little purple, to a dark purple containing a little blue. When burnished it acquires a beautiful, glossy, copper tint. It is generally thought that its specific gravity should be less than that of water, though the method of preparation and adulteration with foreign matters often cause it to weigh more than an equal bulk of that liquid. Many methods for estimating the absolute amount of colouring matter—*indigotin*—in a specimen of indigo have been proposed, but they all require experience in chemical manipulation for their accurate performance: they will be found described in the various analytical text-books.

The great value of indigo as a dyeing material, and the enormous extent to which it is used, have procured for it a large share of the attention of scientific chemists. The result is that its application as a pigment has been greatly extended, and many important and interesting derivatives obtained from it. The following list will exhibit at a glance the relations which the chief of these derivatives bear to each other. Starting with pure indigo itself (indigotin), which may be looked upon as a positive radical, and which we may represent by the symbol (In=*indyl*), we have :—

Indigo-blue	$C_{16}H_5NO_2$	= In
White indigo . . .	$C_{16}H_6NO_2$	= In, H
Sulphindigotic acid . . .	$C_{16}H_5NO_2, S_2O_6$	= In, S_2O_6
Isatin	$C_{16}H_5NO_4$	= InO_2
Isatic acid	$C_{16}H_7NO_6$	= HO, InO_3
Isathyd	$C_{16}H_6NO_4$	= InO_2H
Indin	$C_{32}H_{10}N_2O_4$	= In_2
Hydrindin	$C_{32}H_{11}N_2O_4$	= In_2H

Indigo-blue or *indigotin* ($C_{16}H_5NO_2$), may be obtained in a very beautiful form by mixing commercial indigo with about half its weight of plaster of paris and sufficient water to make a thick cream; this is evenly spread over an iron plate so as to form a stratum about one-eighth of an inch in depth, and set aside to dry. A spirit or gas flame is then applied to the under surface of the plate when the indigo sublimes out from the mixture and condenses in brilliant little purplish-brown crystals, on that part of the plaster immediately over the source of heat. By gradually moving the lamp the indigo is sublimed in successive portions that readily admit of being removed by a spatula from the hard cement below. Indigo-blue thus produced is very beautiful, but not pure. To obtain it in the latter state, it is necessary to dissolve it in a dilute alkaline solution, and as indigo itself is not soluble in such a menstruum, it is brought into intimate contact with some substance that is capable of furnishing hydrogen to it, hydride of blue indigo being thus formed which is quite soluble. One of the best methods of accomplishing this is the following. Four parts of indigo in powder, four parts of grape sugar, and ten parts of a saturated solution of caustic soda, are placed in a flask of such a size that it will hold about twenty times the volume of the mixture. The vessel is now filled up with boiling alcohol, well stoppered, briskly agitated, and set aside. The liquid soon becomes clear, and is then poured out into shallow vessels and exposed to the air, when it rapidly absorbs oxygen and deposits crystals; these when washed, first with alcohol and then with hot water, form perfectly pure indigo blue.

Indigo-blue is a neutral body, tasteless and inodorous. It is insoluble in water, alcohol, ether, oils, dilute acids, or alkalies. It fuses and sublimes in purple-coloured vapours at about 550° Fahr.; at a higher temperature it is decomposed, hydrocyanate and carbonate of ammonia, aniline, and an empyreumatic oil being among the the volatile products, while much carbonaceous residue remains.

White Indigo, Indigogen, or (improperly) *Reduced Indigo* ($C_{16}H_6NO_2 = C_{16}H_5NO_2,H$) is a combination of hydrogen with indigo blue, and may be prepared by several processes: all of which, however, depend upon the deoxidising effect they have upon water, the hydrogen of that compound being thus furnished to the indigo. Grape sugar is such a deoxidising or hydrogenising agent, and if to the dilute alkaline solution (already referred to in the description of the method for obtaining pure indigo blue) there be added acetic acid, dirty white flocks of indigogen are precipitated. White indigo is insoluble in water, slightly soluble in alcohol and in ether, and when exposed to the air rapidly absorbs oxygen, forming water and indigo-blue.

The solubility of white indigo in a dilute alkaline solution, and the insolubility of blue indigo in a similar menstruum, are facts of great interest and importance, as on them depend the use of indigo in the arts of dyeing and calico-printing. The deoxidising agents, other than grape sugar, that are used for making the *reduced indigo vats*, are protosulphate of iron, protochloride of tin, orpiment, and decaying vegetable matter; lime sometimes replacing the alkali. For details of the preparation of some of these baths or vats, see CALICO-PRINTING and DYEING.

Sulphindigotic acid, or *Sulphindylic acid* $(In,S_2O_6 = C_{16}\genfrac{}{}{0pt}{}{H}{H_4}NO_2,S_2O_6)$. One equivalent of hydrogen in this compound is replaceable by an equivalent of metal, forming salts called *sulphindigotates* or *sulphindylates*. Sulphindigotic acid is formed by dissolving commercial indigo in six times its weight of fuming or Nordhausen sulphuric acid. The product is known as *Saxony blue*, and is extensively used in cloth dyeing; it contains another acid named *hyposulphindigotic acid*, and the greater part of the residue from its preparation consists of *sulphopurpuric* or *sulphophenicic acid* $(2C_{16}H_5NO_2,S_2O_6)$. By the decomposition of these sulphuric derivatives of indigo there are produced *sulphoviridic, sulphoflavic, sulphofulvic*, and *sulphorufic acids*: they have been but little studied.

Isatin $(C_{16}H_5NO_4)$, a substance obtained from indigo by the addition of two equivalents of oxygen.

$$\underbrace{C_{16}H_5NO_2}_{\text{Indigo-blue.}} + O_2 = \underbrace{C_{16}H_5NO_4}_{\text{Isatin.}}$$

In order to prepare it, powdered indigo is to be mixed in water with equal parts of sulphuric acid and bichromate of potash, the last being dissolved in 20 or 30 parts of water. The indigo dissolves, and at first without the extrication of any gaseous matter, but towards the end with the disengagement of carbonic acid gas, and the formation of a deep yellowish brown liquid, from which the isatin separates by evaporation, in crystals; these are purified by repeated crystallisations in water, and one and the last in alcohol. Nitric acid may be used in the place of chromic for oxidising the indigo, but if too concentrated, indigotic acid (nitrosalicylic acid) results.

The properties of isatin are:—It crystallises in prisms, which are of a yellowish red or deep aurora-red colour, possessing much splendour when deposited from an alcoholic solution; they are slightly soluble in cold water, but dissolve readily in boiling water and in alcohol; these solutions discolour the skin, and impart a disagreeable odour to it. The crystals are decomposed by heat, leaving a charcoal which it is difficult to incinerate; the caustic alkalis convert it into isatic acid. Fused with solid hydrate of potash it is decomposed, aniline being produced according to the following equation:—

$$\underbrace{C_{16}H_5NO_4}_{\text{Isatin.}} + 4(KO\,HO) = \underbrace{C_{12}H_7N}_{\text{Aniline.}} + 4(KO,CO_2) + H_2$$

Chlorine and Bromine derivatives of Isatin.—One or two atoms of hydrogen in isatin may be replaced by one or two atoms of chlorine or bromine, and the following compounds formed:—

Chlorisatin	$C_{16}\genfrac{}{}{0pt}{}{H_4}{Cl}NO_4$
Dichlorisatin	$C_{16}\genfrac{}{}{0pt}{}{H_3}{Cl_2}NO_4$
Bromisatin	$C_{16}\genfrac{}{}{0pt}{}{H_4}{Br}NO_4$
Dibromisatin	$C_{16}\genfrac{}{}{0pt}{}{H_3}{Br_2}NO_4$

These compounds greatly resemble isatin, both in appearance and in all their reactions. The chlorine derivatives are produced by the action of chlorine upon indigo, and separated by crystallisation from alcohol, chlorisatin being less soluble in that liquid than dichlorisatin. The bromine derivatives are obtained in a similar manner from indigo, using bromine instead of chlorine.

Isatic acid $(C_{16}H_7NO_6 = HO,C_{16}H_6NO_5)$. Isatin dissolves in potash with a deep purple colour, which becomes bright yellow by heat. The solution yields by evaporation a crystalline salt of potash, which is soluble in alcohol, and crystallises in small, hard, colourless prisms. When a solution of this salt is mixed with one of acetate of lead, a white precipitate is obtained, which, diffused in water and decomposed by hydrosulphuric acid, yields a colourless acid liquid, and this by spontaneous evaporation furnishes a white and scarcely crystalline powder, which is hydrated isatic acid.

The properties of isatic acid are as follow:—It is perfectly insoluble in cold water; but when heated in water, it is decomposed into isatin and water, the mixture becoming of a reddish yellow colour: the soluble isatates act in the same manner with the mineral acids; when they are added to it cold, no decomposition is apparent; but as soon as heat is applied, the mixture becomes yellow, and deposits crystals of isatin.

Isatate of potash gives a white precipitate with barytic salts, soluble in boiling water; with the salts of silver it gives a white precipitate, which dissolves when heated in the mixture, a certain portion of the silver salt being reduced to the metallic state; the boiling solution of isatate of silver deposits crystals which are partly in laminæ and partly granular. The general formula of these *isatates* is $(C_{16}H_6MNO_6 = MO,C_{16}H_6NO_5)$.

Chlorine and Bromine derivatives of Isatic Acid.—These are—

Chlorisatic acid	$C_{16}H_6ClNO_6$
Dichlorisatic acid	$C_{16}H_5Cl_2NO_6$
Bromisatic acid	$C_{16}H_6BrNO_6$
Dibromisatic acid	$C_{16}H_5Br_2NO_6$

They are respectively produced by the action of potash upon chlorisatin, dichlorisatin, bromisatin, and dibromisatin, the potash salt of the acids being thus formed, and this, by double decomposition with the soluble salts of other bases, furnishes the several metallic derivatives of these acids.

Ammoniacal Derivatives of Isatin.—Ammonia acts upon isatin, giving rise to bodies that differ from each, according as the circumstances differ under which they are brought into contact. They all contain the elements of isatin, plus ammonia (NH_3) and minus water (HO). Their relations to each other are best shown by formulating them upon the ammonia type, or upon the hydrated oxide of ammonium type, as follows, in which blue indigo—that is, the radical *indyl* $(C_{16}H_5NO_2)$—is represented by the signs (InIn or In_2).

Imesatin	$C_{16}H_6N_2O_2 = N\begin{cases}In\\In\\H\end{cases}$
Imasatin	$C_{32}H_{11}N_3O_6 = \left.\begin{matrix}NIn_4O\\H\ O\end{matrix}\right\}$
Isamic acid	$C_{32}H_{13}N_3O_8 = \left.\begin{matrix}NIn_2H_2O\\H\ O\end{matrix}\right\}\ \left.\begin{matrix}InO\\InO\end{matrix}\right\}$
Isamide	$C_{32}H_{14}N_4O_6 = \left.\begin{matrix}NIn_2H_2O\\NIn_2H_2O\end{matrix}\right\}$
Isatimide	$C_{48}H_{17}N_5O_8 = \left.\begin{matrix}NIn_4O\\NIn_2H_2O\end{matrix}\right\}$

Each of the chlorine and bromine derivatives of isatin gives rise to a similar class of bodies, in each of which, of course, isatin is replaced by the chlor or brom derivative.

Imesatin is obtained in colourless prisms on passing a current of dry ammoniacal gas through a solution of isatin in absolute alcohol. *Imasatin* is produced when a solution of isatin in ammonia is maintained for a short time at the boiling point. It crystallises in lamellar grains. *Isamic*, called also *imasatic* and *rubendinic acid*, crystallises out in beautiful plates from an alcoholic solution of isamate of ammonia, to which hydrochloric acid has been added. Isamate of ammonia results from the metamorphosis of isatate of ammonia when a solution of the latter salt is evaporated to the consistence of a syrup. Bromine energetically attacks isamic acid, producing a yellow body termed *indelibrome*. *Isamide*, or *amasatin*, is formed when isamate of ammonia is strongly dried. *Isatimide* is a crystalline yellow powder formed during the preparation of imesatin, but is more soluble in the alcoholic ammonia, and therefore crystallises out subsequently to the imesatin. There appear, also, to be produced at the same time, *isatilime* $(C_{48}H_{16}N_4O_{10})$, containing three atoms of isatin, plus one of ammonia, minus two of water; and *amisatin* $(C_{96}H_{39}N_{11}O_{18})$, represented by six atoms of isatin, plus five of ammonia, minus six of water.

Isathyd $(C_{16}H_6NO_4 = C_{16}H_5NO_4, H)$.—This body may be viewed as the hydride of isatin, bearing the same relation to that body that white indigo does to blue. It is best prepared by placing isatin in a flask with zinc and dilute sulphuric acid. It is a grayish crystalline powder, insoluble in water and sparingly so in alcohol or ether. On passing a current of sulphuretted hydrogen through the alcoholic solution, *bisulphysathyd* $(C_{16}H_6NO_2S_2)$ is formed, a body in which two atoms of sulphur replace two of the oxygen in isathyd. On adding solution of potash drop by drop to an alcoholic solution of bisulphisathyd, one atom of sulphur is substituted by one of oxygen, and *sulphisathyd* is produced. By the action of hydridising agents upon the chlorine and bromine derivatives, corresponding *chlor* and *brom isathyds* are obtained.

Isatane $(C_{32}H_{12}N_2O_6)$ is a white powder, formed when bisulphisathyd is boiled with bisulphite of ammonia. It contains the elements of two molecules of isathyd, less two atoms of oxygen.

Indin is prepared by the action of potash on sulphisathyd, the alkali being subsequently removed by hydrochloric acid. It is pulverulent, of a very fine deep rose-red colour, insoluble in water, and slightly soluble in alcohol and ether. When heated, it begins to swell as soon as it melts. It yields a substance which crystallises in needles, and much charcoal remains. Boiling nitric acid decomposes it, altering its colour slightly, red vapours are formed, and *nitrindin* $(C_{32}H_9(NO_4)N_2O_4)$ is produced. If the ebullition be continued, the new product is also decomposed, and disappears. Sulphuric acid dissolves indin, assuming a red colour, and water precipitates it from solution unaltered; bromine colours it violet. Ammonia has no action on indin, but potash attacks it under certain circumstances. It is polymeric with blue indigo, and its probable composition is $(C_{32}H_{10}N_2O_4)$.

Indinic Acid is formed in combination with potash, yielding black crystals, by the continued action of the alkali upon indin; the indinate of potash is readily decomposed by water, and still more easily by acids; alcohol dissolves a little of it, but by long washing decomposes it. In the air it becomes of a light rose colour. Its composition appears to be ($C_{32}H_9KN_2O_4$).

Chlorine and Bromine Derivatives of Indin are produced by the action of heat on the corresponding derivatives of isathyd.

Hydrindin ($C_{64}H_{22}N_4O_8 + 2Aq.$) appears to contain the elements of indin plus hydrogen. It occurs in small white prismatic crystals, and is prepared by acting upon indin with an alcoholic solution of potash. The re-action also gives rise to *flavindin*, a body forming pale yellow acicular crystals.

INDIGO-BLUE. [INDIGO.]

INDIGO-WHITE. [INDIGO.]

INDIGOGENE. [INDIGO.]

INDIGOTIC ACID. [INDIGO.]

INDIGOTIC GROUP. According to Gerhard's system of classification of organic compounds, this group, belonging to the BENZOIC SERIES, consists of a number of bodies derived exclusively from indigo, under which the individual members of this group will be found described. Indigotic compounds possess a certain relation to salicylic, kinonic, and phenylic compounds. Thus salicylic acid, nitrosalicylic acid, perchlorokinonpicric acid, and aniline, can be obtained from indigotic compounds; but when once thus broken up, no indigotic body has yet been reproduced from these derivatives.

INDIGOTIN. [INDIGO.]

INDIN. [INDIGO.]

INDINIC ACID. [INDIGO.]

INDUCEMENT. [PLEADING.]

INDUCTION (ἐπαγωγή), as defined by Archbishop Whately, is "a kind of argument which infers respecting a whole class what has been ascertained respecting one or more individuals of that class." According to Sir William Hamilton the word has been employed to designate three very different operations:—1. The objective process of investigating particular facts, as preparatory to Induction, which he observes is manifestly not a process of reasoning of any kind; 2. A material illation of a universal from a singular, as warranted either by the general analogy of nature or the special presumptions afforded by the object matter of any real science; 3. A formal illation of a universal from the individual, as legitimated solely by the laws of thought and abstracted from the conditions of any particular matter. The second of these operations is the inductive method of Bacon, which proceeds by means of rejections and conclusions, so as to arrive at those axioms or general laws from which we may infer by way of synthesis other particulars unknown to us, and perhaps placed beyond reach of direct examination. ('Nov. Org.,' 'Aph.,' c. iii., c. v.) Aristotle's definition coincides with the third, and induction "is an inference drawn from all particulars." ('Prior Analy.,' ii., c. xxiii.) The second and third processes are improperly confounded by most writers on logic, and treated as one simple and purely logical operation. But the second is not a logical process at all; since the conclusion is not necessarily inferrible from the premise, for the *some* of the antecedent does not necessarily legitimate the *all* of the conclusion, notwithstanding that the procedure may be warranted by the material problem of the science, or the fundamental principles of the human understanding. The third alone is properly an induction of logic; for logic does not consider things, but the general forms of thought under which the mind conceives them; and the logical inference is not determined by any relation of causality between the premise and conclusion, but by the subjective relation of reason and consequence as involved in the thought. The inductive process is exactly the reverse of the deductive; for while the latter proceeds from the whole to the part, the former ascends from the part to the whole: since it is only under the character of a constituted or containing whole, or as a constituent and contained part, that anything can become the term of logical argumentation. Of these two processes, Sir William Hamilton gives the following figures:—

Induction.	Deduction.
X Y Z are A.	B is A.
X Y Z are whole B.	X Y Z are under B.
∴ whole B is A.	∴ X Y Z are A.
or,	or,
A contains X Y Z.	A contains B.
X Y Z contains B.	B contains X Y Z.
∴ A contains B.	∴ A contains X Y Z.

This confusion of material and logical induction led Gillies and others to insist on the sameness of the Baconian and Aristotelian induction; while Campbell and Dugald Stewart, who totally mistook the value of all logical inference, yet rightly maintained their difference.

By Aristotle, induction and deduction are viewed as in certain respects similar in form; but in others as diametrically opposed, the latter being an analysis of the whole into its parts, by descending from the more general to the more particular; but the former descends by a synthetical process from the parts to the whole. The logicians, who misapprehended the nature of induction, reduced it to a deductive syllogism of the third form, and thereby overthrew the validity of all deduction itself, since the latter is only possible by means of the former, which legitimates the proposition from which its reasoning proceeds.

Again, the Aristotelian induction was drawn from all the particulars, whereas the confusion which Sir W. Hamilton has pointed out gave rise to a division of the inductive process into perfect and imperfect, according as the enumeration of particulars is complete or incomplete. The latter gives only a probable result, whereas the necessity of the conclusion is essential to all logical inference, as its demonstrative stringency depends upon the form of the illation, and not upon the truth of the premises. It is proper to add, that no one ever knew the distinction between the imperfect and perfect forms of the conclusion better than Aristotle himself.

INDUCTION (Mathematics). The method of induction, in the sense in which the word is used in natural philosophy, is not known in pure mathematics. There certainly are instances in which a general proposition is proved by a collection of the demonstrations of different cases, which may remind the investigator of the inductive process, or the collection of the general from the particular. Such instances however must not be taken as permanent, for it usually happens that a general demonstration is discovered as soon as attention is turned to the subject.

There is however one particular method of proceeding which is extremely common in mathematical reasoning, and to which we propose to give the name of *successive induction*. It has the character of induction as defined by the logicians, because it is really the collection of a general truth from a demonstration which implies the examination of every particular case; but it adds to the necessary character of induction that each case depends upon one or more of those which precede. Substituting demonstration for observation, the mathematical process is truly inductive. A couple of instances of the method will enable the mathematical reader to recognise a mode of investigation with which he is already familiar.

Example 1.—The sum of any number of successive odd numbers, beginning from unity, is a square number, namely, the square of half the even number which follows the last odd number. Let this proposition be true in any one single instance; that is, n being some whole number, let 1, 3, 5, ... up to $2n+1$ put together give $(n+1)^2$. Then the next odd number being $2n+3$, the sum of all the odd numbers up to $2n+3$ will be $(n+1)^2+2n+3$, or n^2+4n+4, or $(n+2)^2$. But $n+2$ is the half of the even number next following $2n+3$: consequently, if the proposition be true of any one set of odd numbers, it is true of one more. But it is true of the first odd number 1, for this is the square of half the even number next following. Consequently, being true of 1, it is true of $1+3$; being true of $1+3$, it is true of $1+3+5$; being true of $1+3+5$, it is true of $1+3+5+7$, and so on *ad infinitum*.

Example 2.—The formula x^n-a^n, n being a whole number, is always algebraically divisible by $x-a$.

$$\begin{aligned} x^n-a^n &= x^n-a^{n-1}x+a^{n-1}x-a^n \\ &= x\,(x^{n-1}-a^{n-1})+a^{n-1}\,(x-a) \end{aligned}$$

In this last expression the second term $a^{n-1}(x-a)$ is obviously divisible by $x-a$: if then $x^{n-1}-a^{n-1}$ be divisible by $x-a$, the whole of the second side of the last equation will be divisible by $x-a$, and therefore x^n-a^n will be divisible by $x-a$. If then any one of the succession

$$x-a,\ x^2-a^2,\ x^3-a^3,\ x^4-a^4,\ \&c.$$

be divisible by $x-a$, so is the next. But this is obviously true of the first, therefore it is true of the second; being true of the second, it is true of the third; and so on, *ad infinitum*.

There are cases in which the successive induction only brings any term within the general rule, when two, three, or more of the terms immediately preceding are brought within it. Thus, in the application of this method to the deduction of the well-known consequence of

$$x+\frac{1}{x}=2\cos\theta,\ \text{namely,}\ x^n+\frac{1}{x^n}=2\cos.\,n\,\theta,$$

it can only be shown that any one case of this theorem is true, by showing that the preceding two cases are true; thus its truth, when $n=5$ and $n=6$, makes it necessarily follow when $n=7$. In this case the two first instances must be established (when $n=1$ by hypothesis, and when $n=2$ by independent demonstration), which two establish the third, the second and third establish the fourth, and so on.

An instance of mathematical induction occurs in many equations of differences, in every recurring series, &c.

INDUCTION, ELECTRICAL. [ELECTRICITY, COMMON; GALVANISM; MAGNETO-ELECTRICITY.]

INDUCTION. [BENEFICE.]

INDULGENCE is a power claimed by the Roman Catholic church, of granting to contrite and confessed sinners remission of the penalty, or part of the penalty, which they ought to suffer here or hereafter in expiation of their sins. The indulgence does not remit the guilt, "culpa," nor the eternal punishment awarded to the impenitent sinner, but only the temporal penalty which the repentant sinner, after having duly confessed his sins and received absolution, has still to undergo, either in this world or in purgatory, according to the belief of Roman Catholics. [Confession.] In the early ages of the church repentant sinners after confession had to undergo public punishment, often very severe, in proportion to their offences; such punishments, however, were occasionally mitigated by the "indulgence" of the bishops, who, in particular cases, abridged the austerities enjoined by the canons, or commuted them for works of charity and pious exercises. Such was the origin of indulgences. (Maldonat, 'De Indulgentiis; Bibliothèque Sacrée,' par les Pères Richard et Giraud, article 'Indulgence;' Lingard, 'History of England,' vol. iv.)

Several of the early fathers of the church, such as St. Cyprian ('De Lapsis') and Tertullianus ('De Pudicitia'), complained of the abuse of this practice in their time, and especially that simple priests presumed to grant indulgences, which was the exclusive privilege of bishops, and that bishops themselves granted them with too much facility. The canonical or ceremonial penalties becoming in course of time disused, together with the practice of public confession, the indulgences which continued to be granted afterwards were understood to remit that part of the penance to be undergone in purgatory which was equivalent to the canonical penalty which would have been awarded by the early church. (Maldonat.) "The faith of Catholics," says Maimbourg ('Histoire du Luthéranisme,' vol. i.), "has always been that the Son of God has conferred on his church the power of relieving the penitent sinner not only from the bonds of his sin by the merits of Christ's passion applied to him in the sacrament of confession, but also from the punishment which he would suffer, either in this world or the next, as a satisfaction to the divine justice for offences committed after baptism. Hence St. Paul, at the request of the Corinthians, remitted to the incestuous man whom he had excommunicated, the remnant of the penalty incurred for the crime; hence the bishops of the earliest ages gave peace to apostates, and reconciled them to the church by abridging the time of the criminal penance through the intercession of martyrs, and in virtue of their sufferings, joined to those of the Saviour of the world, who rendered them precious in the sight of God." The 'Bibliothèque Sacrée,' above quoted, contains a most elaborate article on the subject of indulgences, divided into eight sections, namely—1. On the name and nature of indulgences. 2. On the various sorts of indulgences. 3. On their virtues and effects. 4. On their truth and foundation. 5. On the causes of indulgences. 6. On the subjects or persons to whom indulgences are applied. 7. On the conditions and dispositions required in order to obtain the benefit of the indulgences. 8. On the abuse of indulgences. We may observe on this last point that indulgences are granted in some cases to those who give money for the building of churches and other pious purposes; but that the sale of or traffic in indulgences has been severely reprobated by many councils, and that the bulls of indulgences granted by the Pope contain the clause that "if any thing be given as the price of this indulgence, the indulgence itself becomes null." The sale of indulgences, however, has on many occasions been connived at by the higher authorities in the Romish church, and, as is well known, it was the indignation excited by an act of this kind which first aroused the anti-papal spirit in Luther, and led eventually to the Reformation.

INEQUALITY. (Astronomy.) For convenience, the average motion of a planet or satellite, supposed to be made in a circle which has the average distance of the body from the sun or primary for its radius, is the first object of calculation when the place of the body at some future time is to be predicted. All the alterations which are rendered necessary by the unequal motion of the planet are called inequalities. [Gravitation; Lunar Theory; Planetary Theory, &c.]

INERTIA. This word means something equivalent to the modern English sense of *inactivity*, or rather of *incapability*, and expresses that property of matter by which it does not change its own state of rest or motion, but requires for that purpose the action of some external cause, to the magnitude of which the change is in proportion. Previous to some remarks upon the use of this word, we shall give at length the third definition of Newton's 'Principia,' from which the common usage of it is derived. "The *vis insita*, or innate force of matter, is a power of resisting by which every body, as much as in it lies, endeavours to persevere in its present state, whether it be of rest or of moving uniformly forward in a straight line. This force is ever proportional to the body whose force it is; and differs nothing from the inactivity of the mass, but in our manner of conceiving it. A body, from the inactivity of matter, is not without difficulty put out of its state of rest or motion. Upon which account this *vis insita* may, by a most significant name, be called *vis inertiæ*, or force of inactivity. But a body exerts this force only when another force, impressed upon it, endeavours to change its condition," &c.

We could wish that the use of this word were entirely exploded, and for the following reason. When a term is proposed to stand for a property, mode of being, or condition of existence, about which we know nothing except that certain phenomena always occur under certain circumstances, such a proposition may be listened to, on condition that there is one distinct phenomenon or class of phenomena, which wants a distinctive name, and also on condition that the word is to be used in a purely characteristic, and not in a doctrinal or explanatory sense. Thus the word *impenetrability* [Impenetrability], though likely to cause misconception, as pointed out in the article cited, is nevertheless a good word to those who know how to use it, and a necessary word to those who desire to describe and reason on our knowledge of matter. It conveys to the mind, by one act of separation or abstraction, the notion of a cause for a phenomenon which might be conceived to exist independent of the other properties of matter. We can imagine impenetrable space, not endowed with mobility, colour, or any other accident of matter. But with the word inertia as used by Newton, we do not describe any quality of matter, but supply a term of causation for matter itself, so far as those properties are concerned which are studied in mechanics. What is the *matter* of a work on pure statics or dynamics? That which obeys certain three laws of motion, or presents phenomena which are of a certain threefold description. What word, according to Newton, should be used as a term of causation to remind us that the first law of motion arises from something inherent in the constitution of matter? The inertia, or vis inertiæ. What for the second law? The inertia. What for the third law? Still the inertia. Consequently, this inertia is literally nothing but an expression of the incapability of matter to obey any other laws except those which it really does obey; and the policy of admitting such a term is not merely a question of mechanics. Need we accompany every fundamental term of every science by another, which merely expresses that there must be some reason why the thing signified has the collection of properties which it is found to possess, and not any other? We think the answer must be in the negative, in which case the word matter itself may be substituted for inert substance, the two phrases being perfectly interchangeable in every work on mechanics. [Motion, Laws of.]

If the word inertia be admitted at all as one of distinction, it must be to separate the object of geometry from that of mechanics. In the former we consider space only, that is, bounded portions of space: in the latter we suppose this bounded space to have inertia. But the distinction is quite sufficiently made without the introduction of a synonymic. In geometry we consider space without reference to the question, whether the space be vacuum or matter; in mechanics we consider matter.

Thus much for the use of inertia in a scientific sense: in many popular writings we find it applied as a sort of explanation of the properties of matter, which are so and so *because* matter has inertia. Since this vicious application of words is not by any means confined to the case before us, it is needless to enlarge upon it.

There is one use of the word inertia which is convenient and harmless, namely, as part of the phrase MOMENT OF INERTIA. If we imagine a material system which admits of revolution about a fixed axis, it is obvious that the more closely the matter of which it is formed is collected about the axis the less resistance will be offered to the production of rotatory motion. The law of this resistance will be explained in the article alluded to.

INFAMY (from the Roman Infamia) in English law is not easily defined. Certain offences were formerly considered of so heinous a nature that conviction and judgment for them rendered a man infamous and incompetent to be a witness. But the endurance of the punishment, or reversal of the judgment, restored a man's competency as a witness. The 9 Geo. IV. c. 32, § 3, enacts, that when a man convicted of a felony shall have undergone the legal punishment for it, the effect shall be the same as a pardon under the Great Seal; and (§ 4) no misdemeanour, except perjury or subornation of perjury, shall render a man an incompetent witness after he has undergone his punishment. The 6 & 7 Vict. c. 85 (introduced into the House of Lords by Lord Denman, and carried into law after great discussion) was the Act by which many of the old abuses in our rules of evidence were remedied, and the views of the advocates of reform were carried out. This Act, which is entitled 'An Act for Improving the Law of Evidence,' after remarking on the obstructions in the way of eliciting truth in courts of justice owing to incapacities created by the existing law, and the desirability that those who have to decide on the facts in issue should exercise their judgment on the credit of the witnesses, enacts that no person offered as a witness is to be excluded on account of incapacity from crime or interest from giving evidence, either in person or by deposition, on the trial of any issued joined, &c., but that every such person may be admitted to give evidence on oath or affirmation, notwithstanding such person may have been convicted of any crime or offence. [Evidence.]

Certain offences enumerated in the 7 & 8 Geo. IV. c. 29, § 9, are infamous crimes, with reference to the provisions of that Act. Though infamy does not disqualify a man from being a witness, it may be urged as an argument against his credibility, for, as an American judge has said

"It is perfectly safe and most conducive to the purposes of justice, to trust the jury with a full knowledge of the standing of a witness into whose character an inquiry is made. It will not thence follow that from minor vices they will draw the conclusion in every instance that his oath must be discredited, but only be put on their guard to scrutinise his statements more strictly, while in cases of vile reputation in other respects they would be warranted in disbelieving him, though he had never been called so often to the book as to fix upon him the reputation of a liar when on oath." (Hume *v.* Scott, 3 A. K. Marshall, 261.) As to this branch of the English law of evidence, see Taylor on Evidence, vol. ii. §§ 132—1328; and Best on Evidence, 2nd edit., pp. 184—187.

The only satisfactory definition of infamy would be a permanent legal incapacity to which a man is subjected in consequence of a conviction and judgment for an offence, and which is not removed by suffering the punishment for the offence. By 2 Geo. II. c. 24, § 6, persons who are legally convicted of perjury or subornation of perjury, or of taking and asking any bribe, are for ever incapacitated from voting at the election of members of parliament; and by 17 & 18 Vict. c. 102, s. 6, it is enacted that after a conviction of any person, if a voter, in a court of law for bribery or undue influence, or after judgment in a penal action for bribery, treating, or undue influence, the revising barrister is to expunge the offender's name from the list of voters, to disallow it when sought to be inserted there, and (in either of the last two events) to place it in a list to be entitled 'The List of Persons Disqualified for Bribery, Treating, or Undue Influence.' Such persons are therefore infamous: they labour under infamy, and have lost part of their political rights.

The Roman term Infamia is the origin of our term infamy. Infamia followed in some cases upon condemnation for certain offences in a judicium publicum; and in other cases it was a direct consequence of an act, as soon as such act became notorious. Among the cases in which Infamia followed upon condemnation, were, insolvency, when a man's goods were taken possession of by his creditors in legal form and sold; the actio furti, and vi bonorum raptorum: actio fiduciæ, pro socio, tutelae, &c. In all these cases a judicial sentence, or something analogous to it, was necessary, before infamia could attach to a person. Among the cases in which infamia followed as an immediate consequence of acts which were notorious are the following: the case of a woman caught in adultery, of a man being at the same time in the relation of a double marriage, of prostitution in the case of a woman, or of a man or woman gaining a living by aiding in prostitution.

Savigny, in his review of the different circumstances which led to the penalty of infamy among the Romans, points out two elementary principles common to them all. First, that infamy always attached to the *personal* act of the individual declared infamous; secondly, that it was in consequence of his *act* and not owing to the *nature of the penalty*, that the offender was adjudged to be infamous. (D. 3, 2, 22.)

The consequence of Infamia was incapacity to obtain the honours of the state, and probably the loss of the suffrage also; and it was perpetual. The infamis was still a citizen (civis), but he had lost his political rights. The infamous man was also under some disabilities as to his so-called private rights. He was limited by the Prætor's edict in his capacity to postulate (that is, take the initial measures for asserting or defending his rights in legal form), to act as the attorney of another in such cases, to be a witness, and to contract marriage.

The rules of the Roman law as to Infamia are chiefly contained in the 'Digest,' iii. tit. 1 and 2, and Code, ii. tit. 12. In addition to these texts contained in the Corpus Juris Civilis, the reader is referred to the old fragmentary Roman law called the 'Tabula Heracliensis,' published at Rome about the year 709, under the name of the Lex Julia Municipalis, which will be found to bear upon the authorities above referred to.

(See Savigny, *System des heut. Röm. Rechts*, ii. § 76–83; Becker, *Handbuch der Röm. Alterthumer*, ii. 121; Puchta, *Institutionem*, ii. 441; Muhlenbruch, *Doctrina Pandectarum*, vol. ii. §§ 189 *et seq.*)

INFANT, a person under the age of twenty-one, whose acts are in many cases either void or voidable. As a general rule, an infant cannot make any binding contract, though to this there are some exceptions: thus an infant may bind himself to pay for his necessary meat, drink, apparel, physic, and such other necessaries, and likewise for his good teaching and instruction. But where an infant is living in his father's house and under his care, he is not liable even for necessaries. Necessaries for an infant's wife are necessaries for him. Infants are also incapacitated from making a will.

It should also be observed, that an infant, how young soever he may be, and even a child in the womb, or, as it is technically expressed, *en ventre sa mere*, may be appointed an executor: but the statute 38 Geo. III., c. 87, disqualifies an infant who is appointed *sole* executor from exercising the office during his minority; and administration with the will annexed must be granted to the infant's guardian, or to some other person, until the infant is of full age.

An infant en ventre sa mere is supposed in law, for most purposes, to be a person in being. Thus he may take an estate, and the taking away of his life may amount to homicide.

INFANT HEIR. [HEIR.]

INFANT SCHOOLS. [SCHOOLS.]

INFANT WITNESSES. [AGE.]

INFANTICIDE. The practice of putting infants to death has existed from the remotest periods on record, though the motives for the act have somewhat varied. In some at least of the states of Greece the destruction of those who were born weak or deformed was either commanded or allowed. In Rome children were exposed or put to death, not only with the view of removing those who might throughout life have remained a burden to their friends and useless to the state, but to prevent the too rapid increase of the population. The propagation of Christianity first checked the practice; and in A.D. 315, Constantine the Great provided for the maintenance of the offspring of those who were themselves destitute. Infanticide prevailed however to a slight extent till the reign of Valentinian, who "included such murders in the letter and spirit of the Cornelian Law." (Gibbon, 'Decline and Fall.') Among the contemporary barbarous nations, the same motive, and the sacrifices required for their deities, induced the same crime.

In modern times, the practice, though it is not anywhere sanctioned or commanded by law, is yet permitted in many countries. In China a large proportion of the female population are put to death as soon as they are born. Among the Hindus it was practised to a very great extent, till the Marquis of Wellesley, when appointed Governor-General of India, used every possible exertion to put a stop to it. By the perseverance of Major Walker and others his endeavours were successful, though unhappily for only a short time, for Bishop Heber tells us that "since that time things have gone on very much in the old train, and the answer made by the chiefs to any remonstrances of the British officers is, 'Pay our daughters' marriage portions, and they shall live.'" ('Narrative of a Journey in Upper India,' and 'Hindu Infanticide,' by E. Moor, F.R.S., 1811; including Walker's 'Report.') On the island of Ceylon, Heber also remarks that in 1821 "the number of males exceeded that of females by 20,000; in one district there were to every hundred men only fifty-five women, and in those parts where the numbers were equal the population was almost exclusively Mussulman." Here also, as in Hindustan, the difficulty and expense of educating female children, and the small probability of their marrying without some dowry, while a single life is deemed disgraceful, are the motives leading to the perpetration of the crime. Amongst the Mohammedans the practice is not discountenanced, though the necessity for it is greatly lessened by the habit of producing abortion, which almost universally prevails. In the numerous islands of the Pacific, infanticide is practised to such an extent, that some of them have at times, when pestilence has contributed its influence, been nearly depopulated. When Cook visited Otaheite, he found its population to be upwards of 200,000; but in the early part of this century it was reduced to between 5000 and 6000, and this principally from the practice of murdering their offspring. Mr. Ellis ('Polynesian Researches') says that he does "not recollect having met with a female in the island, during the whole period of his residence there, who had been a mother, while idolatry prevailed, who had not imbrued her hands in the blood of her offspring." We have similar accounts from nearly all the northern parts of America, from Hudson's Bay, Labrador, Mexico, &c.; but it is most gratifying that in all, one of the first and greatest blessings which have followed the introduction of Christianity and civilisation has been the decrease or complete cessation of this abominable custom.

In more civilised lands, although infanticide is regarded with the deepest abhorrence, and is visited with the extremest severity of the law, the expense and trouble of maintenance, and the fear of shame and loss of reputation, are motives sufficiently powerful for the occasional perpetration of the crime.

It is one of the most difficult questions of medical jurisprudence to discover and establish the murder of a child lately born. The chief points for decision are, 1st, whether the infant, the subject of inquiry, was born dead or alive; and 2nd, whether its death was the result of violence or of natural causes.

To establish the former point it is necessary to prove first that the infant was not born before the end of the sixth month after conception, because before that time a fœtus cannot be deemed capable of maintaining an independent existence, or to be what is called *viable*. This being proved from the size and form of the child, the decision whether it were born alive or not must generally rest on the condition of the lungs and heart, in which certain remarkable changes are produced as soon as respiration in the air has commenced. In the fœtus in utero and in the still-born child the lungs are of a dark purplish or chocolate colour, nearly like that of the liver; they are small, and occupy only a small part of the cavity of the chest, in which they lie close against the spine; they have a firm solid consistence, like liver, and their edges are sharply lobed. In the child which has breathed the lungs are of a florid red or rosy hue; they nearly fill the chest, and are found on opening it to be almost in contact with its front wall: their substance is soft, spongy, and light—they crepitate or crackle when pressed, frothy fluid may be squeezed out from an abundance of minute cellules, and their edges and lobes, instead of being sharp, are smoothly rounded off. If the child has breathed fully for some minutes after birth, these characters will generally be sufficient to decide the point in question, but in more difficult cases the weight of the lungs and their specific gravity require to be examined. At the same time that the air enters the lungs in respiration, a much larger quantity of blood is sent to them from the heart than had before circulated through them, and they therefore become considerably heavier. Ploucquet has on this ground proposed what is called the Static Lung Test, which is applied by comparing the absolute weight of the lungs with that of the whole body. By subsequent observers it has been determined that the weight of the lungs of still-born children is somewhat less than $\frac{1}{70}$ of that of the whole body, and that of the lungs of children that have breathed, rather more than $\frac{1}{35}$. This difference, though not sufficient to make this test by itself decisive, is yet of much importance as an addition to other evidence, and is especially to be considered in connection with the hydrostatic test, which is founded on the specific gravity of the lungs. As the air and blood enter the lungs at the same time, their relative weight is diminished, although their absolute weight is increased; so that a portion of the lung of a still-born child is heavier than a portion of the same size from a child which has breathed. The former is heavier, the latter lighter than water; and hence a simple test is obtained by observing whether the lungs of the infant under examination will float or sink when thrown into a vessel of water. When carefully employed, these two tests cannot fail to decide whether the child has breathed or not, but there are circumstances which may in some degree obscure the evidence to be drawn from them. First, there are those circumstances which may cause the lungs of a child which has never breathed to float in water. A certain degree of putrefaction may do this, by the quantity of gas which is generated in their tissue. This however cannot take place until the whole body of the infant is extremely putrid, for the lungs are amongst the organs which remain longest unaltered after death. Nor could a competent person fail to discover the difference between lungs rendered light by putrefaction and those which had breathed; the former present large bubbles of gas on their surface, which may be squeezed out by pressure under water, and when this has been done, the portion of lung to which they were attached will immediately sink. In some very rare cases emphysema of the lungs is produced during birth, but this also can at once be known by the air being contained in large bubbles, from which it may be pressed out. Lastly, the lungs may have been artificially inflated after death, but in this case the alteration of colour and volume, though produced in the same manner as in natural respiration, are only partial; some portions of the lungs are spongy and ruddy, but others are solid and livid. All the doubt that might arise from any of these circumstances may be removed by cutting up the lungs into small portions and squeezing each piece firmly under water: if natural respiration has been performed the smallest portion of lung, unless torn by the continued pressure into mere shreds, will continue to float; but in every other case the air may be so completely expelled that every portion will sink. In no case moreover, except where natural respiration has taken place, will the absolute weight of the lungs be increased; for in no other does the increased flow of blood from the heart take place.

On the other hand, there are very rare cases in which, though the child was born alive, the lungs will not float. They may be diseased, or the infant may have been too feeble to breathe completely, but in both these cases the same plan of cutting each lung into small pieces and testing each will remove all doubt, for there will be at least some portions into which the air has entered sufficiently to inflate them completely. The static and hydrostatic tests therefore, when carefully employed together, will prove whether the child have breathed, but they afford no evidence as to whether it was murdered or not. For it may have breathed during birth, and have died before it was completely born; or, on the other hand, it may have lived for a short time without breathing. These cases are however exceedingly rare, and their occurrence is so clearly indicated by the appearances found on the body, that they rarely embarrass the evidence that is given.

The signs of a child having lived after birth, which are to be found in the heart and other parts, afford no positive information unless life has continued for at least a day, and then the lungs alone will always suffice for decision. We need not here consider the evidence required to prove whether a child born alive was murdered, or died from natural causes, for it must be similar in all respects to that which is necessary in cases of homicide. [Homicide.]

Law relating to Infanticide.—If the result of the evidence be that the child was born alive, and that it was destroyed, the offence is murder, and punishable accordingly. [Murder.] If a woman be quick with child (that is, if she has felt the child move within her), it is a felony if she take, or any person administer to her, or use any means to procure abortion, and is punishable by penal servitude for life.

The murder of bastard children by the mother was considered as a crime so difficult to be proved, that the statute 21 James I., c. 27, made the concealment of the death of a bastard child absolute evidence that it had been murdered by the mother, except she could prove, by one witness at least, that it had been actually born dead. This cruel law was mitigated by the 43 George III., c. 58; and now, by the statute 9 George IV., c. 31, s. 14, the concealment of the body of a bastard child is declared to be a misdemeanour, and made punishable by imprisonment for any term not exceeding two years, with or without hard labour.

These are the regulations of the English law directly designed to prevent infanticide. There are however institutions in this country, as well as many other European countries, which have been founded with the view of restraining the commission of the crime, of which an account is given in the article Foundling Hospitals: but the history of these establishments shows that though they may have rendered infanticide less frequent, they have by no means tended to preserve the lives of illegitimate children; for in all of them, except the London Foundling Hospital, which is a comparatively wealthy establishment, their records show an astonishing amount of mortality, in some cases as high as eleven-thirteenths.

INFANTRY is a name given to the soldiers who serve on foot. It is immediately derived from the Italian word *fante*, which, though in strictness denoting a child, is in general applied to any young person. From the latter word comes *fantaccino*, and this is the origin of *fantassin*, a name which was once so commonly applied to a foot-soldier. During the time that the feudal polity was in vigour the numerous dependants of the nobility served in the wars, for the most part, on foot; and being called children, because they were so considered with respect to their patron lords, or to the towns from whence they were drawn, the word infantry became at length the general name for that species of troops. Boccaccio, who wrote in the 14th century, designates by the word *fanteria* the men who marched on foot in rear of the cavalry.

Among the ancient nations of Europe the foot soldiers constituted the chief strength of the armies. In the best days of the Grecian and Roman states battles were mainly won by the force and discipline of the phalanges and legions, and the number of the infantry in the field far exceeded that of the cavalry. The cavalry were then, as at present, employed chiefly in protecting the wings of the army and in completing the victory which had been gained by the infantry. It may be remarked also that most of the writers on tactics, from Folard downwards, express a decided preference in favour of the infantry.

The French historians agree that the ancient Franks, when they left the forests of Germany, were accustomed to march and fight on foot; and they persevered in this practice even after they had obtained possession of the country of the Gauls, which abounded with horses. In this country also the greater part of the Anglo-Saxon forces consisted of infantry, the cavalry being formed of the thanes, or rich proprietors of the land: the infantry were divided into heavy and light armed troops; the former being provided with swords and spears and large oval shields, and the latter having only spears, clubs, or battle-axes.

But soon after the time of Charlemagne the institutions of chivalry began to be generally adopted in the kingdoms of Europe. These led to frequent and splendid exhibitions of martial exercises on horseback in presence of the sovereigns and assembled nobles; and the interest inspired by the achievements of the knights on those occasions was naturally followed by a high regard for that order of men. By degrees the cavalry, which was composed of persons possessing rank and property, and completely armed, acquired the reputation of being the principal arm in war; and the foot soldiers, ill armed and disciplined, were held in comparatively small estimation.

From the capitularies of the French kings of the second race it appears that the foot soldiers who served in the armies of France consisted of slaves and freed serfs: the latter were either peasants or artificers, who, for the benefit of the army, occasionally exercised their particular trades, as shoeing horses, forming intrenchments, &c.; and, in action, like the men of the inferior class, were employed as skirmishers or light-armed troops. Similarly the infantry of this country, for some time after the Conquest, consisted of the yeomanry, vassals and dependants of the feudal tenants; and occasionally foot soldiers were engaged by the kings, under indentures, to serve in the wars. The English troops at that time wore a plain iron helmet called a *bascinet*, and a linen doublet stuffed with wool or cotton; their arms were generally pikes, but frequently they had swords and battle-axes.

Under the third race of kings in France the possessors of fiefs were not compelled to furnish infantry for the armies; and it appears that this duty was then imposed on the towns. The troops thus raised were obliged to serve only in or near the towns to which they belonged; or, if they were marched to a considerable distance from thence, they received pay. In the reign of Philip Augustus this militia must have been very numerous; for in some districts it was formed into legions, and was commanded by persons of distinction. At the battle of Bovines (1214) the municipal militia formed the first line of the French army, but it was defeated by the German infantry which was more numerous, and even then of better quality, than that of France.

In 1448, Charles VII. instituted the militia denominated *Francs Archers*, which consisted of 16,000 foot soldiers armed with bows. But this body existed only about 40 years, when it was suppressed by Louis XI., who formed a standing army of 10,000 French infantry, to which were joined 6000 Swiss; and subsequently Charles VIII. added a large body of Lansquenets, or German infantry. The reputation of the native troops in France seems to have been then at a low ebb; for Brantôme, in his 'Discours des Colonels,' describes them as being mostly the refuse of society—men with matted hair and beards, who for their crimes had had their shoulders branded and their ears cut off. On the other hand the Swiss soldiers were inured to discipline; they were protected by defensive armour and formed into deep battalions, in which state they were able to render the shock of cavalry entirely unavailing. Large divisions of these troops accompanied the army of Charles VIII. into Italy, in 1494, where their good conduct and discipline greatly contributed to raise the reputation of the infantry to its ancient standard.

The superiority of this class of troops consists in their being able to act on ground where cavalry cannot move; and it is obvious that the latter must, at all times, have been nearly useless in the attack and defence of fortified castles or towns. Even when the cavalry were held in the highest estimation it was sometimes found convenient for the knights to dismount and act as infantry. Froissart relates that at the battle of Cressy the English troops were formed in three lines, consisting of men-at-arms who fought on foot and were flanked by archers. At Poitiers and Agincourt also the men-at-arms engaged in a similar manner.

The Spanish soldiery, probably from being almost constantly engaged in warfare with the Moors, had early acquired considerable reputation; and the gallantry of the troops on foot, in keeping the field after the cavalry had retired, has been supposed, though this opinion of the origin of the name is now rejected as fanciful, to have been commemorated by the designation of infantry, which was bestowed upon them, it is said, in consequence of their having been headed on that occasion by an Infanta of Spain. The great share which the Spanish forces had in the wars carried on both in Italy and Flanders during the reigns of Ferdinand, Charles V., and Philip II.; their steady discipline, and the success which resulted from the association of musketeers with pikemen in their battalions, caused the infantry of Spain to be considered, during many years, as the best in Europe. But the rivalry in arms between the Emperor Charles V. and Francis I. of France, and the connection of Henry VIII. of England with both, led, in the several states of those monarchs, to the adoption of the improvements which had been introduced by the Spaniards. It may be added that the practice of keeping up standing armies composed of men trained in the arts of war under a rigid system of discipline, together with the universal adoption of the musket, has now brought all the infantry of Europe to nearly the same degree of perfection.

In 1859 the English army numbered 86,983 infantry troops, exclusive of engineers and artillerymen, many of whom serve on foot: besides those serving in India, under the name of the East Indian Army.

INFECTION is the contamination of the atmosphere or other inert substances by the deleterious or offensive qualities of malaria, the matter of contagion, effluvia from putrid animal or vegetable substances, &c. Some of these are at once recognised by the smell, or by chemical analysis, but the presence of others is known only by the diseases which they produce. The same means however may be applied in many cases for preventing the injurious effects of both classes.

The most important and valuable method of disinfection is ventilation, and, whatever other may be added to it, this should never be neglected. The apartment, or whatever requires to be purified, should be exposed to a constant and free current of fresh air, till every trace of odour is completely expelled, or as long as any emanation is going on. The reputation of chlorine, acids, lime, charcoal, &c., as disinfectants, depends on their property of decomposing the offensive gases which are so often mixed in the atmosphere with the matter of infection, but it is questionable whether they have any influence on the infectious particles themselves. However as the emanations from putrid substances render the body peculiarly liable to the reception of infection, some of these means should be employed where any offensive smell is present. Fumigations with aromatic substances, as camphor, &c., are perfectly useless, only serving to conceal the smell, but having no influence either on it or the infectious particles. Perfect cleanliness is of the greatest importance; every portion of the room or house should be carefully and frequently washed with hot soap and water; clothes and everything removable should be immersed in hot water, and after being well washed should be exposed for a long time to the open air, or sprinkled with chloride of lime; the walls and ceilings should be whitewashed, and beds, bedding, &c., cleaned and exposed in the open air. Dr. Henry has rendered it probable by numerous experiments that the infectious qualities of substances which cannot be conveniently washed, as trunks, packages of valuable merchandise, &c., may be sufficiently destroyed by exposing them to a dry heat of 200° for not less than an hour.

The following are some of the agents which are employed for the purpose of destroying infectious matters of various kinds:—

Chlorine.—This gas has a great affinity for hydrogen gas [CHLORINE], and as the latter forms so conspicuous an element in infectious compounds, they are destroyed when exposed to the agency of chlorine. Chlorine is especially applicable where infectious substances exist in the atmosphere. It may be employed by generating it from the decomposition of common salt with peroxide of manganese and oil of vitriol, or by mixing red lead with dilute muriatic acid. These preparations however require caution, and the more common plan is to use the solutions of chlorinated lime or soda. These solutions may be applied to floors, and vessels may be rinsed out with them. They may be diluted and linen rinsed out in them.

Permanganates of soda and potash.—These substances are powerful oxidisers. Wherever animal and vegetable matters exist in a state of decomposition, they oxidise the hydrogen and nitrogen, forming nitric acid and water. They are sold under the name of "Condy's disinfecting fluid," and are exceedingly useful where solid or liquid infectious matters have to be dealt with. They speedily render the matter of cesspools, drains, and sewers, perfectly innocuous. They may be also employed for the purification of water, and by their action on organic matters, can be employed as a test for the purity of water. The disinfecting quality of permanganic acid depends on the presence of ozone in this acid, which is readily given up to the organic matters with which it comes in contact.

Chloride of zinc.—This substance has the power of arresting change in decomposing animal and vegetable substances, and may be employed for this purpose, but it does not act so perfectly as the foregoing substances.

Perchloride of iron.—The salts of iron have all a great power of combining with organic matters, and arresting the progress of decomposition, and also of destroying infectious matters. It is one of the cheapest substances that can be employed for disinfection on a large scale, and is the compound recommended to the Metropolitan Board of Works for deodorising the Thames.

Sulphurous acid.—This acid is formed by leaving sulphur in the open air, and acts as a disinfectant by combining with oxygen, and becoming converted into sulphuric acid. It cannot however be used in rooms where persons are breathing on account of its suffocative action.

Salts of various kinds arrest decomposition, as nitrate of potass, chloride of sodium, sulphate of zinc, &c., but are not to be recommended as disinfectants.

Coal tar, Creasote, and Carbolic acid have all a power of combining with animal and vegetable substances and preventing their decomposition. Creasote is especially recommended to prevent the smell from cancerous sores.

INFEFTMENT, in the law of Scotland, from the same origin as the English term feoffment, expresses the ceremony by which a person succeeding to another by descent, settlement, or conveyance, is invested in any heritable or real property. This ceremony was, until quite recently, as pure a feudal usage as it ever had been in the days when the almost universal inability to write suggested symbolical modes of changing possession. A number of persons had to proceed to the ground, consisting generally of the solicitor who prepared the titles, and his clerks, who had the following parts to act. One was the bailiff of the superior, and a commission authorising him to act in that capacity was read over. Another party acted as the procurator or representative of the purchaser. The bailiff lifted some fragments of earth and stone from the soil and handed them to the procurator, as symbols by which, according to the authority given to him, he made over possession of the lands to the new owner. The receiver of the symbols then placed a coin of the realm in the hands of another party, who must have been a notary public—this being the form in which a protest is taken in the hands of a notary in Scotland. Two other parties acted as witnesses. The ceremony, with the authority on which it proceeded, was narrated in a deed called an instrument of sasine, in which the notary publicly attested the transaction. The preservation of this cumbrous ceremony down to so late a period was owing to its connection with the admirable system of registration which has kept the commerce in real property in Scotland on so clear and secure a position; for the whole ceremony went for nothing unless the instrument were recorded in the Register of Sasines within sixty days after the ceremony. This registration was, and in modern usage is, the criterion of preference; for the person whose sasine is first registered has the absolute title, all questions as to the fairness of the transaction being pecuniary questions to be settled apart from the title to the lands. The cumbrous ceremony mentioned above has been rendered unnecessary by modern legislation. Conveyances and other deeds are now, in most cases, registered themselves; the public registration of the deed, or of instruments setting out the nature thereof, or otherwise analogous to the instrument of sasine, coming in place of the infeftment and registration formerly in use.

INFINITE, INFINITY, INFINITESIMAL, INFINITESIMAL CALCULUS. The word infinite is literally "without bounds," and when applied in an absolute sense to magnitude means that its quantity is utterly unlimited, so that there is no conceivable and determinable magnitude but what is less than the infinite magnitude.

The notion of infinity is therefore at first purely negative, but it does not long remain so: for we are forced upon what we take the liberty of calling a definite notion of infinity, by our consideration of time, space, and number. We cannot, if we would, annihilate our conception of space, or confine it within certain limits; nor can we suppose duration to have an end. Even if we imagine our own annihilation we cannot rid ourselves of the idea of something else existing, with the permanent conception of unbounded space and time. If we try to conceive all sentient existence at an end, we know from reasoning that it may be we ought to suppose also the annihilation of space and time: but the constitution of our minds will not permit it, and so long as we exist to think, even about our own non-existence, the reality of space and time will prevent our conceiving their destruction. Whether the preceding be good or bad metaphysics is perfectly indifferent in an article on the use of the word infinite in the exact sciences: the ideas expressed, true or false, are those which will, in the first instance, present themselves to the mind; and those who object to one method of expression will embody the same thoughts in another.

The other extreme in the scale of quantity is the perfect absence of all magnitude, expressed in the word "nothing" or the technical term "zero." It is necessary to treat the two together in mathematical reasoning, since all difficulties which belong to the one term belong equally to the other. We have also to consider the words "infinitely small" as well as "infinitely great."

There are three distinct methods of proceeding in regard to the employment of these terms in mathematical reasoning. Firstly, we have those who would use the words "infinite" or "nothing" in their absolute sense, relying upon the reality of the conception which they have of the things signified by them. Secondly, there are others who would entirely banish the use of the words, because in their absolute sense they do not represent assignable magnitudes. Thirdly, others admit the use of the words, guarding them by definitions which point out the processes in the expression of the results of which they may be employed.

To the first it is answered that the absolute use of ∞ and 0 (the mathematical symbols of infinite magnitude and absence of all magnitude) in the same manner as symbols of definite quantity, is extremely liable to lead to error; which was never entirely avoided by the advocates of this system, except by abandoning their theory, and applying in practice the maxims alluded to under the third of the preceding heads. The absurdity of an absolute and unrestricted use of these terminal symbols may be very easily shown, if it be maintained that they are to be used precisely as other symbols. For example, it will readily be conceded that if a times x be y, and if b times x be y, then a and b must be equal. Now twice an infinite magnitude is infinite, and three times an infinite magnitude is infinite, therefore 2 and 3 must be asserted to be equal. The advocates of the unrestricted use of ∞ and 0 avoid such results by a method of selection which amounts to keeping within the definition presently to be noticed.

To the second of the three sects above mentioned it may readily be conceded that they have a right to refuse any branch of mathematical reasoning, so far as themselves only are concerned. But we deny that the code of mathematical controversy contains any such axiom as that "mathematics is the science of assignable magnitudes only," by which to claim the submission of an opponent. The general rule is, that mathematical demonstration exists wherever there is logical deduction from universally obvious maxims with respect to magnitude. Nor does the word "universally" here mean that such maxims must have been obvious to every individual of the human race. If so there would be no such thing as mathematical demonstration: for there have been found instances in which persons have denied that the sum of all the parts makes up the whole. It would not be very easy to lay down a rule by which it should be determined what fraction of dissent is fatal to an axiom, but the following appears to us to be the practice. When any individual who has been successful in advancing the mathematical sciences, and whose talent and originality are widely known, disputes what is usually received as a first principle, it is customary for subsequent writers on the same subject to preserve his objections, and place them before the reader. If two or three such persons unite in an objection, the fact of there being a majority of the same class on the other side would not save the principle attacked from being considered as dubious. All differences which affect results are very soon settled; but those which only array one mode of attaining a certain conclusion against another, depending as they do for the most part upon the manner in which fundamental and indefinable terms are understood, are generally perpetuated from one age to another. Now it is a proposition which is very rarely disputed, that the science of mathematics is conversant with more than assignable magnitude, and that the notion of infinity, though requiring to be used with care, is one with regard to which sound and obvious maxims of reasoning may be laid down.

We proceed to state these principles, that is, to enunciate the method followed by the third of the sects mentioned. If we look at the manner in which we derive the notion of infinity, we shall not find any one who imagines that he absolutely grasps infinite space, time, or number, by one single and independent conception of his mind. To space, space may be added, to this again space may be added, and so on without limit, until the space thus accumulated is greater than any definite space [INDEFINITE] which was named at the outset of the process. From thence comes the notion of infinite: we cannot imagine the greatest possible space, because any space, however great, being distinctly conceived, we can as distinctly conceive a greater. Consequently the phrase "space is infinite," whatever more it may imply, certainly may be allowed to stand for an abbreviation of the preceding two sentences. And in like manner, if we see a conclusion—which we can nearly attain by the use of a large magnitude, more nearly by the use of a larger, and so on without limit, that is to say, as nearly as you please, if we may use a magnitude as large as we please, but which is never absolutely attained by any magnitude however great—then such conclusion may be said, for abbreviation, to be absolutely true when the magnitude is infinite. It may appear to some as if the conclusion, under the preceding circumstances, is really true when the magnitude is infinite: this may or may not be the case, but the mathematical use of the word infinite does not require the question to be raised. The convention under which that term is introduced demands that the preceding conditions shall be fulfilled, and excludes the word whenever they are not fulfilled: those who think that the fulfilment of the conditions makes that which we call a convention a necessary consequence, meet on common ground with those who would reject the absolute notion of infinity. The former are allowed their own words, and their own result, together with their own method of arriving at it; the latter are not required to use the word infinite, except as an abbreviation: to the mere collocation of the letters which compose that word they can hardly object, and the conditions of its introduction are precise and intelligible. We shall now give a few instances of the development of propositions in which the word infinite appears.

1. When z is infinite, A is equal to B. This may be said in abbreviation of the following:—When z is great, A is nearly equal to B; A may be made as nearly equal to B as you please if we may take z as great as we please; but no value of z, however great, will make A absolutely equal to B.

2. A finite quantity x, divided by an infinite quantity, is nothing. If x be divided by a comparatively great quantity, the quotient is small; this quotient may be made as small as you please, if we may take the divisor as great as we please; but no divisor, however great, will make the quotient absolutely equal to nothing.

3. Every circle is a regular polygon of an infinitely great number of infinitely small sides. An inscribed polygon of a large number of small sides nearly coincides with the circle; a polygon may be made to coincide with the circle as nearly as you please, if its number of sides may be as great as we please, and their lengths as small as we please; but no polygon, however great its number of sides, and however small the sides, can absolutely coincide with the circle.

4. When x is infinite A and B are both infinite; but A is infinitely greater than B. This may be said when if x increase, A and B both increase, so that A and B may both be made greater than any quantity you name, provided we may make x as great as we please: provided also that A increases faster than B, so that when you name any number, however great, we, being allowed to make x as great as we please, can make A contain B more than that number of times.

5. When $x=a$, z is infinite. This may be said when z is great if x be nearly equal to a, and may be made as great as you please, if x may be made as nearly equal to a as we please: provided that, however near x may be to a, z has still an assignable value.

The preceding instances are sufficient to show what is meant when the terms "infinity," "infinite," or "infinitely great," appear: we now proceed to the correlatives "nothing," "infinitely small," "evanescent," &c. The independent use of the term "infinitely small," as laid down by some writers, is yet more difficult than that of infinitely great. If A be an assignable magnitude, x is said to be infinitely small when it is so small that it is absolutely incomparable to A, so that $A+x$ and A may be taken as equal. Now, unless x be absolutely equal to nothing, this cannot be; so that the infinitely small quantity, as thus defined, can have no magnitude whatever. Here we seem to rest, not in an absurd, but in a useless conclusion: for what possible benefit can arise from inventing a new word to stand for the *nothing* by which two equal magnitudes differ. A little further consideration of the term "nothing" will here be necessary.

There is one process of arithmetic which yields an absolute zero, namely, subtraction. From a take a, and nothing remains. Consequently, in considering the idea of the absence of all magnitude, we usually refer it to the result of that process by which it is directly and unambiguously obtained. But from no other process of arithmetic does this idea arise, except by the same train of ideas which leads us to the use of the word infinite. We cannot, for example, obtain the quotient "nothing" by dividing one finite magnitude by another; we can make the result small, smaller, as small as we please, but not absolutely nothing. When therefore we consider an equation made by addition and subtraction of terms, the absolute result 0 may be used without reservation: thus, $2x+3=a$, and $2x+3-a=0$, may be written for each other without any particular examination of the symbol 0. But in any other case we can only consider 0 as the limit towards which we approach by an interminable succession of diminutions, no one of which is ever final, corresponding to the interminable succession of augmentations by which we attain the notion of infinite. In strict analogy therefore with our former proceeding (mutatis mutandis, we repeat our words) if we see a conclusion—which we can nearly attain by the use of a small magnitude, more nearly by the use of a smaller, and so on without limit, that is to say, as nearly as you please by the use of a magnitude as small as we please, but which is never absolutely attained by any magnitude however small; then such conclusion may be said, for abbreviation, to be absolutely true when the magnitude is nothing. The sentences immediately following the first occurrence of the preceding words may now be repeated, only changing "infinite" and "infinity" into "nothing."

But in the meanwhile the term infinitely small does not appear, and its use seems to be superseded by that of the word "nothing." And it is true that "nothing," introduced under the preceding conditions, might supply the place of an infinitely small quantity. But since there is an absolute use of the term "nothing," derived from subtraction, to which the mind clings, and of which we do not find the like in connection with the term infinity, we shall, after some further explanation, use the term infinitely small instead of "nothing."

Our explanation of the term infinite will readily show the meaning of the following assertion; two infinitely great quantities may have a finite ratio. As follows:—when A and B are great their ratio may be nearly, say that of 10 to 7; when they are still greater they may be still more nearly in that ratio, and so on; and their increase may be so regulated that the greater they become the more nearly is their ratio that of 10 to 7; or as nearly as you please, if they may be as great as we please. Similarly, strictly remembering the preceding conditions for the introduction of the word "nothing," we may allow of the introduction of the following phrase:—two nothings may have a finite ratio. This means that A and B, both diminishing together, may diminish in such a way that when both are small their ratio may be nearly, say that of 5 to 3; when they are still smaller they may be still more nearly in that ratio, and so on: and their diminution may be so regulated that the smaller they become the more nearly is the ratio that of 5 to 3; or as nearly as you please, if they may be as small as we please.

But the idea of two nothings which have a finite ratio, however strictly defined in accordance with the preceding conditions, shocks even many of those who can grasp the method of using the word "infinity." The absolute nothing of subtraction has possession of the field, and it is not worth while to contest it for the use of a word. The term "infinitely small" therefore supplies the place of "nothing" whenever the latter is introduced under the conditions correlative to the conditions under which the use of infinitely great is allowed. But it must be remembered that if the infinitely small quantity thus introduced be added to or subtracted from a finite quantity it makes no change in the latter; just as if it were the nothing of arithmetic. A few instances of the development of propositions will now be given.

1. When A is infinitely small B is infinitely great. As A diminishes B increases, and B can be made as great as you please, if A may be taken as small as we please.

2. An infinitely small arc of a curve is equal to its chord. The smaller the arc the more nearly are the two in the ratio of 1 to 1; and the ratio may be made as nearly as you please that of 1 to 1, if the arc may be taken as small as we please.

3. Of two infinitely small quantities, one may be infinitely smaller than the other. When two magnitudes, A and B, diminish together, the smaller they are made the greater may be the ratio of A to B, in consequence of B diminishing much faster than A; and it is possible that A may be made to B in as great a ratio as you please, if both may be made as small as we please. The sine and versed sine of an angle are instances. Both diminish without limit with the angle; but the smaller the angle the greater the number of times which the sine contains the versed sine; and this to any extent whatever.

Infinitely small quantities thus used have been called infinitesimals, and a succession of infinitely small quantities, each of which is infinitely smaller than the preceding, is said to be a series of infinitesimals of different orders. Such a series is x, x^2, x^3, &c., in which, by making x sufficiently small, any one may be made to contain the next as often as we please. The infinitesimal calculus is a name sometimes given to the differential calculus, when presented by means of the theory of infinitely small quantities, in the manner originally propounded by Leibnitz.

The preceding considerations refer to the substance of nearly all the disputes which have arisen about the first principles of the differential calculus [DIFFERENTIAL CALCULUS]; and the different systems noticed in that article (with the exception of that of Lagrange [FUNCTIONS, THEORY OF]), spring out of different views of the manner of presenting the same idea.

In the article ANGLE we have taken notice of the circumstance that an extension of the word "equal" to infinite spaces which coincide, would allow of a proof of the well-known assumption of Euclid. [PARALLELS.] Let us suppose two equal angles having their sides infinitely extended. We have then two infinite spaces, of which it may readily be proved that either may be made to coincide with the other throughout its whole extent. And if any two angles be taken, and infinite spaces be drawn, it may be easily shown that the infinite space of the greater angle is greater than the infinite space of the less. The comparison of such infinite spaces is therefore possible consistently with perfect clearness in the meaning of the terms employed, and a simplicity of reasoning which would convince any one who is capable of the most ordinary thought. Had Euclid been accustomed to the modes of thinking which involve the idea of infinite magnitude, under any form whatsoever, it may be reasonably suspected that he would have admitted the following axiom, "Magnitudes which can be made to coincide in all their parts are equal," as applicable to infinite as well as finite spaces. Not having done so, the adherence to his standard has to this day excluded the only proof of the theory of parallels which does not assume the axiom of Euclid or an equivalent. For demonstration see PARALLELS.

There is a word which confusion of ideas is bringing into use in the sense of infinitely small; namely, *homœopathic*. The confusion is as follows. The system of medicine called *homœopathy* (which means *treatment by similarity*), proceeds upon the doctrine that diseases can be cured by use of the medicines which would produce *similar* diseases in a healthy person. But the homœopathic practitioners *also* hold that excessively small doses, millionths, billionths, decillionths, of grains, are sufficient for cure. The general public, which more readily apprehends the unusually small amount of the doses than the principle on which they are given, has accordingly appropriated the word *homœopathic* as a synonyme of *infinitesimal*.

INFLAMMATION (from *inflammo*, to burn). When any part of the body is preternaturally hot, red, swollen, and painful, such a part is said to be inflamed, or in a state of inflammation; and when these symptoms prevail to a certain extent, or affect very sensible parts, that general constitutional disturbance called fever is excited.

Inflammation may be either acute or chronic, circumscribed or diffused, common or specific. The term common, or healthy inflammation, is applied to all those inflammations which occur in a person otherwise healthy, which run a regular course, are usually of an acute character, and terminate in one of the conditions hereafter to be described. Specific, or unhealthy inflammation, unless produced by the direct action of a morbid poison, as that of syphilis, variola, &c., never takes place in a healthy individual, but is always modified by some pre-existing peculiarity or abnormal condition of the system, frequently hereditary, and is generally chronic. Although pain, heat, redness, and swelling, characterise inflammation in its most ordinary forms, it is by no means uniformly attended with all these symptoms; this is a circumstance which depends on the anatomical structure of the part affected, and on the duration and kind of the inflammation.

Terminations.—Inflammation is said to terminate in three ways:—by resolution, suppuration, and mortification. By the first, which is the most frequent mode of termination, is meant a gradual subsidence of the swelling, a diminution of the heat, pain, and redness, and an abatement of the fever; the parts return to their natural size and colour, and no pus or matter is formed. Suppuration is said to have taken place when the inflammation goes on to the formation of pus; the swelling then becomes more prominent, of a shining red colour, and soft in the centre; if now no artificial opening be made, the matter obtains exit through one or more orifices produced by the absorption of the walls of the cavity in which it is contained, and the abscess, in popular language, is said to have burst. Mortification is the least frequent but most severe mode in which inflammation can terminate, and usually is productive of great constitutional disturbance; when it is the result of a high degree of inflammation, the attendant pain is exceedingly severe, the bright red colour of the part becomes livid, and vesicles form on its surface; complete death of the part then takes place, and the pain abates, but the pulse is small and feeble, and great prostration of strength, with troublesome hiccup, are the constant attendants.

Causes.—The remote or exciting causes of inflammation are produced either by mechanical violence or by the action of chemical or other agents; but it sometimes occurs spontaneously, or without any perceptible cause for its production. With regard to the proximate cause, this is a question which is not so easily solved; it has occupied the attention of pathologists from the earliest times, and the number of theories on this subject attest the number of those who have interested themselves in the inquiry. The older pathologists imagined that all inflammations were produced by a fluxion, or flow of certain humours to a part, and the peculiar nature of the swelling was supposed to depend upon the kind of humour; thus blood produced phlegmon, bile produced erysipelas, &c. After the discovery of the circulation of the blood by our immortal Harvey, Boerhaave appears to have been the first who applied the discovery to the solution of this complicated question; he supposed that the minute blood-vessels became obstructed by the viscidity of the blood, or where this viscidity did not previously exist he imagined that the larger globules of the blood passed into the small vessels and blocked them up. But change in the consistence of the blood being found inadequate to explain all the phenomena of inflammation, it was supposed that the vessels themselves contributed chiefly to its production, and the doctrine of spasm of the extreme arteries began to prevail. Mr. Hunter considered inflammation to be a restorative principle by which injured or diseased parts are repaired, and the act of inflammation he regarded as an increased action of the vessels, which at first consists simply in an increase or distension beyond their natural size.

The application of the microscope to the investigation of the condition of an inflamed part has very materially changed the views of pathologists with regard to the nature of inflammation. If the tissues of an animal in a state of inflammation be examined, the following phenomena may be observed. 1. The capillary vessels of the part are observed to be narrowed, and the blood in consequence flows through them more rapidly. 2. The vessels from being narrower than natural become larger, and now the blood flows through them more slowly but evenly. 3. Changes go on in the capillary vessels, and the flow of blood is observed to be irregular, not even, as in the second stage. 4. If the observation be continued, the blood is seen to be arrested altogether in the capillaries, and these vessels appear to be distended to the utmost. 5. The last and most important phenomenon in the series is, that the liquor sanguinis of the blood is seen to exude through the walls of the blood-vessels, and is sometimes accompanied with the red blood corpuscles, which pass through either the softened or ruptured walls of the capillary vessels. The most important of these changes, and that which perhaps constitutes the essential element of the inflammatory process is the exudation of the lymph or liquor sanguinis.

In view of these phenomena, modern pathologists have adopted many theories with regard to the nature of the changes undergone by the tissues in this state. Whilst some have thought the blood globules themselves were at fault, others have attributed the state to the condition of the nerves of the part, and others again have traced the changes to the condition of the capillary vessels. All however agree, that inflammation involves an altered supply of blood to the inflamed part, and a changed condition of the nutritive processes of the blood.

The results of this process, although summed up in the three terminations before mentioned, may be still further developed. Thus with Mr. Paget, we may divide these effects into *productive* and *destructive*. The productive effects are effusions or exudations which are susceptible of permanent development, and also of degeneration. The destructive effects of the inflammatory process are softening, degeneration, absorption, ulceration and death of tissue, or mortification. We will here merely indicate the nature of these results.

Effusion or *exudation*. According to the tissue in which inflammation occurs, will be the liquid nature of the exudation. In serous membranes the exudation is attended with so much water or serum, that large accumulations of water take place, producing what is called dropsy or effusion. A good example of effusion from inflammation is the action of a common blister. In all cases of effusion of serum, a quantity of fibrin is poured out which is left after the water has been absorbed. This is seen in inflammation of the peritoneum, pleura, and pericardium. The distinction between effusion from obstruction, and effusion from inflammation is, that the latter contains organisable matter, whilst the former does not.

Blood is sometimes effused during the process of inflammation by the rupture of the capillaries. This effusion must not be confounded with hæmorrhage from accidental rupture, which produces quite a different appearance in the part. The latter is bright red, whilst the former is yellow-red or brown.

The plastic matter exuded from the blood-vessels during inflammation is called "inflammatory lymph," or "coagulable lymph," or "exudation." Its most characteristic general properties are, that it is capable of spontaneously organising itself, and that thus organised it may proceed by development to the construction of tissues like the natural structures of the body. It is, however, occasionally modified, and, instead of producing natural structures, it produces structures different from those existing in the body. The exudation, producing new or heterologous formations, has been called by Williams *kakoplastic;* whilst Bennett divides exudation into *simple, tuberculous.* and *cancerous.*

The *simple* variety of exudation produces different results, according to the following circumstances :—

1. The nature of the tissue in which the exudation takes place.
2. The time at which an exudation is examined after its occurrence.
3. The state of the blood in which it takes place, as in small-pox, scarlet fever, &c.
4. The amount of vascularity of the affected part.
5. The amount of local exudation.
6. The suddenness with which the exudation has taken place.
7. The persistence of the inflammatory process.
8. The amount of fluid or water poured out with the inflammatory lymph.

These circumstances modify the appearances which will be presented by an inflamed part, and will also modify to a less considerable extent the local and general symptoms of inflammation.

On examining the lymph or exudation under the microscope, it is found to consist of a liquid containing in it corpuscles which are called "exudation cells." They are rough on the surface, and about the [illegible]th to the [illegible]th of an inch in diameter, and at first present neither a distinct cell-wall nor nucleus, but afterwards a distinct nucleus is seen in them. From the lymph thus constituted proceed all the forms of secondary deposits which are found resulting from inflammation. These primordial cells pass into all the conditions of texture which are found in the tissue in which inflammation takes place, as muscle, nerve, bone, &c.

These cells are exposed to various forms of degeneration. When what is called suppuration comes on they form the "pus cells," and other cells which have been described by microscopic pathologists. Suppuration is either circumscribed, diffused, or superficial. The circumscribed is well seen in the common abscess, boil, or phlegmon. The diffused in phlegmonous erysipelas and purulent infiltration, whilst superficial suppuration is observed in purulent ophthalmia and inflammation of mucous surfaces.

The result of the tuberculous and cancerous forms of exudation is the production of deposits known by the names of cancer and tubercle. [Cancer : Tubercle.]

The destructive effects of inflammation are seen in softening, absorption, ulceration, and mortification more particularly. In softening there is little or no plastic power in the lymph thrown out, and the tissues attached lose their natural cohesiveness. This *softening* occurs in inflammation of the mucous membranes, of the brain and spinal cord, and of the bones. *Absorption* frequently occurs with softening, and this is seen in the common process of the pointing of an abscess, in which the tissues soften and are absorbed.

Ulceration occurs on open surfaces, and is the result of an exudation of inflammatory lymph, in which the corpuscles are formed into pus-cells, and an absorption of the inflamed tissues takes place. Such an absorption may take place entirely independent of blood vessels, as in cartilage, and is nevertheless called ulceration. Granulation is a reparative process that occurs in ulcerated surfaces, and consists in the organisation of the lymph thrown out from the ulcerated surface, and eventually leads to the reparation of the parts destroyed by the softening and absorptive processes. *Mortification* takes place when the vital processes of inflammation cease in a part. Parts more or less extensive, or the whole of an organ may display this tendency. It may be attended with effusion, or it may be dry. All the tissues are liable to the occurrence of this termination of the inflammatory process.

General Symptoms.—The symptoms attendant on inflammation will vary of course with the extent, position, and nature of the local affection. It should, however, be recollected that an extensive inflammation may come on slowly, and not present any general symptoms at all, and that the general symptoms of inflammatory fever may be present without any inflammation. There are however certain general symptoms of inflammation which are so frequently present that they constitute what is called inflammatory symptomatic or sympathetic fever. This fever is attended with premonitory symptoms of coldness and shivering, which are succeeded by a reaction. The pulse, which is at first small and slow, becomes quick and hard. There is thirst, and greatly increased heat of surface. The secretions are diminished, the skin is dry, the bowels are confined, the urine is scanty. There is pain frequently in the loins and head. There are restlessness and anxiety, and occasionally delirium. The respiration is quickened. The tongue is coated, white, and moist. These are the symptoms of inflammatory fever of an active kind, but it is not unfrequent to have this fever from the beginning presenting an adynamic type. This has been named *typhoid inflammatory fever*. It is accompanied with great feebleness. The pulse sinks, the skin becomes moist and cold, the features are pinched, the tongue is dry and becomes black. Low muttering, delirium, and stupor are present. These symptoms may be present from the first, or occur when some unhealthy change takes place in the character of the local inflammation.

Hectic fever is another form of inflammatory fever. It accompanies those conditions of the inflamed part which are called suppurative. This fever is attended with remissions. In the day the fever is slight, but it recurs at night, and is attended with heated skin, and flushed red face, "hectic spots." The fever is at its height at midnight, and is succeeded by colliquative sweats, and frequently accompanied by diarrhœa.

Treatment.—Of course the treatment of inflammation must vary according to its seat, extent, and nature of the general symptoms. When the inflammation is of the simple kind its tendency is towards health, and the less interference there is the better. The great question that has been raised on the treatment of inflammation is the propriety of blood-letting in acute forms attacking important organs. The pathological views given above have greatly modified the notion that bleeding was the best remedy in all forms of inflammation. It does not appear that the abstraction of blood exercises any important influence on the inflammatory process at all, and Dr. Hughes Bennett maintains that its influence on the system is injurious, hence he forbids bleeding for the sake of the inflammation. In certain inflammations, however, as of the lungs, the circulation of the blood is greatly retarded, and in these cases bleeding, by lessening the volume of blood, facilitates the circulation, and is to be recommended. The local abstraction of blood from an inflamed part has also been found to relieve the pain and consequences of the inflammation in a particular organ, and this process is to be recommended where the part can be got at.

Mercury, which was formerly recommended in all inflammations, is now only very cautiously given by some practitioners, under the conviction that it subsequently interferes with healthy nutrition. When given it is seldom pushed so far as to produce salivation. Other remedies for inflammation are tartarised antimony, digitalis, aconite, nitrate of potass, chlorate of potass, saline and other purgatives. The properties of these medicines are treated of under their proper headings, and the treatment of inflamed conditions of the more important organs will be found under the heads of these diseases, or of the diseases of particular organs, as Pleuritis; Peritonitis; Heart, Diseases of; Kidneys, Diseases of; Skin, Diseases of, &c.

INFLEXION. [Diffraction.]

INFLEXION. A point of contrary flexure [Flexure, Contrary] is sometimes called a point of inflexion.

INFLUENZA (*La Grippe*, Fr.). Influenza is the name given by the Italians to an epidemic catarrh, which has spread more extensively than any other epidemic; and this universality of its attacks, together with the greater severity of its symptoms, principally distinguishes it from common catarrh. It attacks all ages and conditions of life, but is seldom fatal except to the aged, or to those previously suffering from or having a tendency to pulmonary disease. Notwithstanding the great frequency of this epidemic, it is remarkable how little variety there has been in its symptoms, and the records of cases which occurred in 1510 nearly resemble those which have been observed during its latest visitations. The following are the symptoms which most generally characterise it:—The person is seized with slight chills; weight and pain, sometimes severe, are felt over the eyebrows; there is an increase of the lachrymal and nasal secretions, with loss of appetite, prostration of strength, a weak frequent pulse, dyspnœa, hoarseness, and cough. When death has taken place, the post mortem appearances have revealed acute inflammation of the mucous membrane lining the air-passages, or pleurisy and pneumonia. The duration of the disease varies from one or two days to a fortnight; but great debility often remains behind for many weeks, and in some epidemics relapses have been frequent.

Several epidemics of influenza have been remarkable for affecting the mucous membrane of the alimentary canal, as well as that of the organs of respiration. The cases occurring towards the subsidence of the epidemic are generally less severe than those at its commencement.

The history of this disease is curious. When once it has made its appearance it pursues a regular course from one country to another, from continent to continent, across seas and over mountains; but this course, although regular as regards each epidemic, yet varies somewhat with most. In 1510 its course was in a north-westerly direction; in 1557 due west, attacking whole populations almost on the same day; in 1580 from east and south to west and north, and was complicated with plague, but France was the only European country infected that year with the latter. The epidemic of 1729 was very fatal in London; Lowe says more persons died of it than at any one time since the plague of 1665. In the month of September, 1729, 1000 weekly were carried off by it in the metropolis. The epidemic of 1803 travelled from south to north. England was also severely visited in 1831, 1833, and 1836–7, and it figures more or less in all the yearly returns of mortality in every year since. It is worthy of note, that in all these epidemics the lower animals have suffered. The destruction of horses and cattle in 1836–7 was very great. Dogs, cats, and birds also suffer, and it is even said fish.

These epidemic visitations have taken place most frequently in the spring and autumn, but have seldom remained at one place longer than six weeks. In 1836 it broke out in Cape Town in Africa at the same time as in London; in the one place it was mid-summer, in the other mid-winter.

On the exciting causes of this, as of all other epidemics, we must confess our ignorance. Some have attributed it to the sudden changes of weather; others to a particular morbid principle, different from but resident in and conveyed by the air; and others again to contagion. The first of these hypotheses is evidently untenable, for atmospheric changes as great and sudden have taken place as some of those observed to precede the breaking out of the epidemic, and yet none has appeared, and an epidemic has occurred without being preceded by any apparent atmospheric peculiarity; the sensible state of the air, too, preceding and accompanying the same epidemic has been different in different places. The doctrine of contagion, although it has had more advocates than either of the former hypotheses, does not appear to rest upon any better foundation. It remains, then, to examine the validity of the second hypothesis—namely, the existence of a morbid principle resident in and conveyed by the air. Now the very doubts on any subject which give rise to theories for explaining the phenomena connected with such subjects presuppose the want of any direct proofs or evidence of a tangible shape; and if—putting aside the idea of the epidemic we are speaking of being caused by any deleterious or unwholesome quality of our food—we allow the atmosphere to be the medium of conveyance of the morbid principle, we must admit that all endeavours hitherto made with the view of demonstrating such principle have only afforded negative results; neither does it appear that there is any one spot on the earth whence it emanates.

However great the discordance of opinion on the cause of this malady, all physicians of eminence have agreed remarkably in their testimony as to the general rules and principles of practice. Notwithstanding the inflammatory nature of this disease, bleeding is ill borne, and can rarely be employed with safety, much less with benefit; and persons who have been subjected to this operation recover more slowly than others, and remain in a debilitated condition much longer. In severe cases, emetics at the commencement have been found useful, either in cutting short the disease or in moderating its violence. Mild aperients administered with caution, the exhibition of antimonial and saline medicines, and a cool temperature, constitute the means which experience has found to be most efficacious during the acute stages of the disease; whilst quinine and stimulants are beneficial in the latter stages.

INFORMATION, an accusation or complaint exhibited against a person for some criminal offence. It differs from an indictment principally in this, that an indictment is an accusation found by the oath of a grand jury, whereas an information is simply the allegation of the officer who exhibits it. Informations are of two sorts: those which are partly at the suit of the crown and partly at that of a subject; and secondly, such as are in the name of the sovereign only. The former are exhibited for numerous offences inferior to felony, as wilful and corrupt oppression by a justice of the peace, libels, conspiracies, &c., and are filed by the master of the crown-office. The latter are filed by the attorney-general at his own discretion, and are called *ex officio* informations. The former kind, which are called criminal informations, can only be filed by leave of the court of Queen's Bench, and the application for leave must be supported by affidavits which the party complained of has an opportunity of answering. When an information of either kind is filed, it must be tried in the usual way by a petit jury in the county in which the offence was committed.

When it is necessary for the Court of Chancery to interfere with the regulation or management of any charity, the attorney-general, on the relation of some informant (who is called the relator), files an information in the Court of Chancery for the purpose of bringing the case before the court.

Proceedings in the Exchequer for the recovery of duties or penalties are also called informations.

INFORMER. An informer is a person who lays an information or prosecutes any person for some offence against the law or a penal statute. Such a person is generally called a common informer, because he is supposed to make a business of laying informations for the purpose of obtaining his share of the penalty. Persons are induced to take the trouble of discovering offences, for which a pecuniary penalty is inflicted on the offender, by the promise of the reward; and if the penalty is imposed for the public interest, he who makes the offender known does the public a service. But still the business of a common informer is looked on with dislike, and he who follows it is generally despised; and perhaps the character of common informers is generally such that they deserve all the odium they receive. They stand in a like situation to the common hangman. This dislike of informers, simply as such, is one of the anomalies of society, who hate their benefactor. The real foundation of the dislike, however, among those who can form a just judgment of things, is, not the act of information, but the devices, tricks, and meannesses to which a man must often resort, in order to know the facts on which his information must be founded. It is the same principle which often leads us to condemn a man for making certain statements in public, not because of the statements, but because of the means by which he may have obtained his knowledge. When a penalty is too heavy, or when the law that imposes it is generally disliked by the people for any reason, good or bad, the popular dislike finds a definite object in the informer who gives effect to the law. The legislature that made the penal law is overlooked, because the legislature is a number of persons; the informer is one, and his agency is seen and felt.

In absolute governments there are spies and political informers, who are the tools of a government which has no rule but its own pleasure. Some people have been dull enough to confound all informers in one class, not seeing that there is a difference between an informer who helps to give effect to the law, and an informer who helps a tyrannical government to entrap and punish persons suspected of disaffection to the government or of designs against it.

INFUSIONS are solutions of some of the principles of vegetables, generally in water, but occasionally in other vehicles. When water is employed it may either be hot or cold. It is customary to use warm water, but in many instances cold is preferable. Where cold water is used, it is necessary to continue the digestion longer than when it is warm. The vegetable substances may either be fresh or dried: when the former, they are to be cut to pieces; when the latter, bruised or very coarsely powdered, never reduced into a fine powder. The water, being poured on the substance employed, is to be allowed to stand in a covered vessel for a space of time varying with the nature of the article submitted to maceration. It must be strained, and is then fit for use. Infusions generally spoil soon, more particularly if warm water be employed, or if the substance contain starch or other fermentable ingredients. Sometimes alcohol is added, after straining, to assist in keeping the infusion, or to increase its powers. Hard water should, if possible, be avoided in the preparation of infusions.

Concentrated infusions, to be diluted to the ordinary strength at the time of employing them, are now prepared on a large scale by wholesale chemists for the use of general practitioners, as they have not only the advantage of keeping better, but avoid trouble and loss of time. Other improvements have been introduced, such as making the infusions by percolation, or, as it is termed by the French, *par déplacement*. Also, Appert's mode of preserving vegetables has been applied [ANTISEPTICS]; and concentrated or preserved vegetable juices have been recommended and adopted by Mr. Squire ('Pharmaceutical Trans.,' No. iii., p. 94, Sept., 1841) and Dr. Bentley. These have many advantages. For infuso-decoctions, see DECOCTIONS.

INGROSSING. [ENGROSSING.]

INHIBITION, in the law of Scotland, is a proceeding by which a creditor may prevent his debtor from alienating property either to favoured creditors or to other persons. Nominally it affects all property; but it is only in the case of real property that, from its being put on the register, it is efficacious. The debt on which inhibition may proceed must be founded on some obligatory written document, or established by the decree of a court. The process may be recalled if improperly awarded. It conveys no specific security to the person who holds it, but it gives him a right to impugn every act which the debtor does to his prejudice after the inhibition. If the inhibition be followed by proceedings to attach the estate at the instance of other creditors, the inhibitor has a preference over them if the debts have been incurred subsequently to the inhibition, but not otherwise. The mixed rights thus occasioned are often productive of very intricate questions.

INJUNCTION *in Equity*. An injunction is a writ, issuing by the order and under the seal of a court of equity, to restrain parties from proceeding in other courts, from negociating notes or bills of exchange to prevent the sailing of a ship, the alienation of a specific chattel, to prevent waste by felling timber or pulling down buildings, the infringement of patents or copyright, to repress nuisances, and to put an end to vexatious litigation. It is impossible here to enumerate the variety of cases in which a plaintiff in equity is entitled to the relief afforded by the writ of injunction.

An injunction may be obtained *ex parte*, and behind the back of the defendant (as the phrase is), immediately after filing a bill, upon motion supported by affidavit; or it may be moved for after the defendant has answered the plaintiff's bill, and on the merits of the case as appearing from the defendant's answer; and if an injunction has been obtained *ex parte*, the defendant may immediately move to dissolve it on affidavits, even before he puts in his answer.

An *ex parte* injunction, that is to say, without notice, cannot be moved for after the defendant has appeared.

INJUNCTION *at Law*. By the Patent Law Amendment Act, 1852, power was given to any court in which an action for infringement of patent should be pending to direct an injunction if it should see fit.

By the Common Law Procedure Act, 1854, courts of common law may grant an injunction, when claimed upon the writ of summons, in cases of breach of contract, or other injury, where the party injured is entitled to maintain and has brought an action. Such injunction is by way of supplement to the common judgment, and is against the repetition or continuance of such breach of contract, or other injury, or the committal of any breach of contract or injury of a like kind, arising out of the same contract, or relating to the same property or right.

This common law injunction has seldom been applied for, or obtained; and a bill has recently been introduced into the House of Lords by Lord Chancellor Campbell, for, *inter alia*, enabling courts of law to grant upon motion exclusive protection against probable violation of legal, as distinguished from equitable, rights. The Roman interdiction was in many respects similar to the injunction. [INTERDICT.]

INJURY, INJURIES. Blackstone, after treating of Rights, proceeds in his third book to "consider the wrongs that are forbidden and redressed by the laws of England." He then divides wrongs into two sorts or species—private wrongs and public wrongs. To private wrongs he also gives the name of civil injuries, as being "the infringement or violation of the private or civil rights belonging to individuals considered as individuals." Public wrongs are "a breach and violation of public rights and duties," and "are distinguished by the harsher appellation of crimes and misdemeanours."

The true nature of *injuria* is, however, contained by implication in another expression in Blackstone: "The contemplation of what is *jus* is necessarily prior to what may be termed *injuria*." For as *jus* is law, so *injuria* is something that is not jus, or is forbidden by jus. An injury, then, in the English law, is some illegal act; but the word is commonly used to express an illegal act done to a man or his property, for which he may by legal process get compensation. The English legal maxim that a man cannot recover damages or compensation when there is a *damnum absque injuria*, contains in it the true meaning of injuria or injury. The act must be an illegal act in order to entitle a man to compensation. If a man's acts damage the property of another, without being such acts as are forbidden, the person who is damaged can get no compensation. For instance, a man may set up a grocer's shop next door to another shop, and get all his neighbour's custom, which is a grievous *damnum*, but no *injuria*. It is true that the nature of the damage may in some cases help to determine whether it is a legal injury or not; but the true question always must be whether the act complained of is either at common law or by statute an injuria, an unlawful act.

The Roman word *injuria*, as already observed, signifies generally anything which is done contrary to law (quod non jure factum est, hoc est contra jus). In its narrow sense, *injuria* was limited to unlawful acts that affected a man's person, not his property, at least not directly. It comprehended personal violence, such as beating a man, and using abusive words to him, and libelling him. Injuria might be done to a man either in his own person or in the person of those who were in his power, as his children and slaves, or in his hand (manu), as his wife. The mode of proceeding was by the *actio injuriarum*. (Gaius, iii. 220–225.)

The nature of Roman *injuria*, in its limited sense, is, therefore, it appears, different from that of injury in English law, as properly understood; for injuries in English law, or civil injuries, or private wrongs, as Blackstone calls them, comprehend all the wrongs that are treated of in his third book—that is, all wrongs except crimes and misdemeanours. The Roman *injuria* belongs both to the head of law criminal and non-criminal. In some cases damages were got; in others, the offender was punished in his person: in some cases he might be punished by a pecuniary penalty and in his person also.

INK, for the various purposes to which it is applied, is composed of very dissimilar ingredients. It may be treated of under the heads of *Writing Ink*, *Indian Ink*, *Printers' Ink*, *Marking Ink*, and *Sympathetic Ink*.

Writing Ink.—The writing ink of the ancients was essentially different from that which is now employed. Its basis was finely-divided charcoal, mixed with some mucilaginous or adhesive fluid; it was much less destructible than modern writing ink, and more resembled printers' ink, both in the nature of its colouring ingredient and its indestructibility.

Writing ink is now a chemical compound, and not a mere mechanical mixture. Its basis is proto-gallate and proto-tannate of iron, which by oxidisement becomes per-gallate and per-tannate; and it is owing to the oxygen of the air effecting this change gradually that recent writing is of a comparatively light colour, and that it subsequently becomes black. Many processes have been given for preparing writing ink. The common ingredients are galls and sulphate of iron; in fact, while printers' ink may be considered as a black paint, writing ink may be regarded as a black dye. The following, which is recommended by Mr. Brande, gives, he says, an excellent ink, and it possesses the merit of greater simplicity than most others:—Aleppo galls, bruised, 6 ozs.; sulphate of iron, 4 ozs.; gum arabic, 4 ozs.; water, 6 pints. Boil the galls in the water, then add the other ingredients, and keep the whole in a well stopped bottle, occasionally shaking it. In two months strain and pour off the ink into glass bottles, which must be well corked. To prevent mould, add one grain of corrosive sublimate, or three drops of creasote, to each pint of ink. Mr. Brande observes, that, "In making good writing ink the great object is to regulate the proportion of sulphate of iron to the galls. If it be in excess, although the ink may at first appear black, it becomes subsequently brown and yellow. Hence some time should elapse before ink is used after the ingredients are put together, in order to be tested from time to time, and the combinations perfectly regulated." Gum is added to retain the colouring matter in suspension, to prevent too great fluidity in the writing, and to protect the vegetable matter from decomposition. Logwood and other vegetable astringents have been tried, but do not yield a permanent ink.

When writing has through age become yellow and indistinct, it is because the vegetable matter has decayed, and mere rust, or peroxide of iron, is left. By carefully applying infusion of galls, the writing may be rendered blacker and more legible. This method was successfully adopted in deciphering the MS. of Gaius, a work on Roman law which attracted great attention among learned men in Germany about forty years ago, and which for a long time resisted all attempts to decipher it. Modern writing ink, unlike the ancient, is readily destroyed by chlorine, acids, and alkalies. Indeed, if paper has been made from inferior rags, bleached by excess of chlorine, the ink, however good, will be ultimately discoloured. Sulphate of copper is occasionally added to ink, and some authorities direct it to be prepared with the addition of vinegar; but these substances are rather injurious than otherwise.

Blue writing ink is now much used; made sometimes from indigo, and sometimes from Prussian blue as a basis.

Indian Ink.—The cakes of this ink are made of lamp-black and size or animal glue, with the addition of perfumes or other substances not essential to its quality as an ink. It is used in China with a brush, both for writing and for painting upon paper of Chinese manufacture. It is used in Europe for designs in black and white, in which it possesses the advantage of affording various depths of shade, according to the degree of dilution with water. The common lamp-black of the shops is not sufficiently fine for the purpose; it requires to be made with peculiar care.

Printers' Ink is of two kinds: for letter-press printing and for copper-plate printing. Printers' ink is prepared by boiling linseed or nut oil in an iron pot; and if it does not take fire of itself, it is kindled, and suffered to burn for about half an hour; the flame is then extinguished by closely covering the vessel; and the oil is by this operation found to have acquired the necessary drying quality, after being again boiled. It is then mixed with a proper quantity of lamp-black, when black ink is required; if red ink be required, the colouring matter employed is vermilion, for finer works. Copper-plate printer's ink is made with oil which is less boiled, and the charcoal used is stated to be Frankfort black, made from vine twigs.

Marking Ink is employed for marking linen: it is a solution of nitrate of silver, written with a pen upon the fabric to be marked, after the latter has been moistened with an alkaline solution, as potash or soda. By this process oxide of silver is precipitated upon and combines with the cloth so as to be scarcely removeable by any re-agent which does not also destroy its texture.

Sympathetic Inks are such as are invisible until heat is applied, and then, by the chemical change induced, the writing becomes visible. The most remarkable of these is that prepared from cobalt, called Hellot's sympathetic ink, which is a chloride of the metal. When the written paper is held to the fire so as to evaporate the water, the letters become green.

The subject of ink has lately undergone much discussion, arising out of a paper read by Mr. Underwood before the Society of Arts. In 1857 the firm of which he is a member was applied to by the Government for an ink that would yield many copies of any written document, by means of some kind of copying machine. It was determined that the ink and the paper should have certain chemical relations, such as that of throwing down a precipitate. The best mode was found to be, to steep the paper in a neutral chromate of potash, and to use a solution of extract of logwood as ink. By preparing three different strengths of solution, it was found possible to obtain from two to twenty copies of any document. A copying-ink has also been prepared, applicable both to printing and writing—a desideratum in many commercial establishments. The printing is first effected; and the ink so printed is rendered partially soluble by moisture when the copying by the press is to be done. Of course the colour and depth of the ink can never be otherwise than faint, by any use of the copying-press. The modern ink-makers candidly admit that the ancients excelled them, in the blackness and durability of their ink. In Durham Cathedral there is a copy of the Bible, written by the Venerable Bede, in which the ink is still beautifully black. Indeed there are numerous MSS. in existence, written from the 5th to the 13th centuries, of which the same may be said. Dr. Lewis, about a century ago, expressed an opinion that the ancient ink consisted of fine charcoal suspended in some mucilaginous fluid; and in this opinion Mr. Astle afterwards supported him. Sir Charles Blagden, some years later, applied chemical tests to many old writings, which afforded proof that the ink was not a mere mechanical mixture, but a true chemical compound. That there were different qualities of ink, then as now, is certain. A parchment document is in existence, written in 1099, containing many certificates written at different religious houses in England; and these, though written nearly at one time, exhibit all shades from faded brown to deep black. Mr. Underwood thinks that some of the old ink was merely a carbon *pigment*, but that other kinds were veritable *dyes* of iron and acids, with a good deal of carbon added.

In reference to printing ink, it may be remarked that the ink of the first *block* books is found usually to be bad; whereas that of the first *moveable type* books is much better—so much so, indeed, as to excel the general kinds of modern ink in depth, brilliancy, and richness of black. Printing ink is, indeed, a compound of very peculiar character; for, in order to be really good, it should possess these four qualities—to distribute freely and work with sharp, defined outlines on the type; to have a greater affinity for the surface of paper than for that of type, in order to transfer readily; to dry much more quickly on paper than on type or an inking-roller; and to be proof against the effects of time and chemical re-agents. We may here state that the bank-note ink, made by Mr. Winstone, is prepared from coal-tar naphtha; this naphtha being burned in close chambers, the smoke or soot is collected, and exposed in a retort to a heat sufficient to drive off all volatile matter; the soot is then ground up with a peculiar varnish, producing a printing ink of intense blackness, which prints off with great fineness of outline, and dries so as to be fit to handle almost immediately.

The miscellaneous kinds of ink, under the names of *japan, invisible, horticultural, lithographic, autographic*, &c., need not be described; they are mostly mere varieties of those already noticed; while one of the number is described under LITHOGRAPHY. *Ink powder*, sometimes useful in travelling, is generally made by mixing the ingredients dry, and adding boiling water in certain proportions when required for use. Leonardi's *alizarine* or *solid ink*, introduced in 1858, at Dresden, is made of Aleppo galls, Dutch madder, sulphate and acetate of iron, and sulphate of indigo, combined into the form of small round cakes; a portion of one of these cakes is dissolved in water when required for use.

INLAYING, is the art of inserting pieces of one substance in cavities cut in the surface of another, as a means of ornament. The substances may be various kinds of metal, or various kinds of wood, or pearl, ivory, tortoiseshell, &c.; and the product may either be regarded as a work of art, or as an ornamental article of furniture. It is in the latter sense that inlaying is chiefly regarded. Two kinds which had much celebrity in their day, but are perhaps less practised at present, are *buhl* and *reisner* work. These were named from two *ébenists*, or cabinet-makers: Buhl, or Boule, an Italian who settled in Paris in the reign of Louis XIV.; and Reisner, a German who settled in the same city soon afterwards. Buhl mostly used a brass inlay on a tortoiseshell ground; Reisner a dark wood inlay on a tulip-wood ground; but it is obvious that the varieties admit of almost interminable change. Where the substances are not too hard to be easily cut, the devices are produced by counterpart sawing; that is, two thin plates are laid one on another, and a very fine saw is worked through both of them, in lines marked out by a pencil device. If we suppose that two veneers or thin layers of wood, one black and one white, were thus treated, there might be two pieces of inlaying produced—the one a black inlay on a white ground, and the other a white inlay on a black ground; for one veneer would exactly fit the holes cut in the other. The saws for this work are mounted in bow or arched handles; they are very narrow and thin, and are worked in short quick movements. In Buhl work, the patterns generally consist of continuous lines, of which the honeysuckle is a familiar example; this does not require the actual separation into small pieces, and thereby marks one point of difference between *inlaying* and *mosaic*. The veneers are temporarily glued together, or rather to a sheet of paper placed between them; the design is drawn on one surface, the material is held loosely in a vice by the left hand, a small hole is made with an awl in a part of the design not very conspicuous, the saw-blade unloosened from its handle is thrust through this hole, the saw-handle is then fixed, and the workman proceeds with his sawing—dexterously turning the saw and the material about so as to make the tortuous cut correspond with the lines of the design. Sometimes three or four veneers are cut in this way, affording means for greatly varying the colours of the inlay.

The ornamental stone-work called *pietra dura* bears more resemblance to inlaying than to mosaic; for the holes are not cut *through* the ground, but only to a certain depth, in slabs of black marble; and small bits of other coloured marble are inserted to this limited depth. The inlaying of knife and fork handles with studs of gold and silver, is similarly effected by drilling holes to a certain depth, and inserting fragments of gold or silver wire. The inlaying of papier-maché with pieces of mother-of-pearl, or other iridescent substances, is not strictly *in*-laying in the sense here employed: for the decorative substance, cut into the forms of leaves, flowers, or other devices, is laid *on* the papier-maché, and a general level produced by many thicknesses of varnish—in the way described under PAPIER MACHÉ.

The delicate fine-art workmanship of mosaic, produced by the juxtaposition of numerous small pieces of enamel, is described under MOSAIC; while the application of wood in ornamental devices to flooring, is treated under MARQUETRY AND PARQUETRY.

In the Jury Reports of the Great Exhibition it is said, in reference to the gold and silver work in the Indian collection:—"Herein the least possible amount of metal is so treated by delicate hand-labour, by exquisite pierced work, enamelling, and *inlays*, combined with such a thorough consideration of the treatment of surface by buhl-work, &c., as to give the greatest amount of skilled workmanship with the smallest quantity of material. . . . . . The Eastern nations largely practise the art of inlaying both in metal and in other materials; their weapons of war are decorated with inlaid work."

INN. The responsibility of innkeepers for the safe custody of the goods and chattels of their guests is one out of the numerous classes of cases that arise upon the law of bailments, and is placed by Sir W. Jones, in his Treatise, under the second subdivision *Locatio Operis*, of the general head *Locatum*. The law makes the innkeeper responsible for the safety of the goods of persons coming to his house, in the language of the ancient writ, *causâ hospitandi;* but he may be released from his liability either by inattention on the part of the guest to such reasonable rules as the innkeeper may think proper to lay down for the protection of the property of his guests,—by any act of negligence on the part of the guest himself,—or by his making use of the house not, as it is before said, *causâ hospitandi.* Thus, if an innkeeper requires his guest to put his goods under lock and key, and the guest leaves them in a passage, whereby they are lost; or the goods are stolen by the guest's own servant; or the guest uses his room in the inn as a show-room, into which a number of people are allowed to have access, and not as a lodging-room, the responsibility of the innkeeper ceases. The general interest seems to require that the law should be made still more strict as against innkeepers, as the good faith and responsibility of the innkeeper form the only security of the traveller. The Roman law on this subject is contained in the Digest iv., tit. 9.

(Smith's *Leading Cases*, 'Calye's Case;' *Treatise on the Law of Bailments*, by Sir W. Jones.)

INNS OF COURT AND OF CHANCERY. The establishment of these houses of law is usually considered to be one of the effects of Magna Charta, which, by fixing the Court of Common Pleas at Westminster, brought together a number of persons who (as Spelman says) addicted themselves wholly to the study of the laws of the land, and no longer considering it as a mere subordinate science, soon raised those laws to that pitch of perfection which they suddenly attained under the auspices of King Edward I. They purchased at various times certain houses between the city of London and the palace of Westminster, for the combined advantage of ready access to the latter and of obtaining provisions from the former. "For their liberties and privileges" (observes Mr. Agard, in an essay written in the end of the 17th century), "I never read of any granted to them or their houses: for having the law in their hands, I doubt not but they could plead for themselves, and say, as a judge said (and that rightly), that it is not convenient that a judge should seek his lodging when he cometh to serve his prince and his country."

In Fortescue's time there were four inns of court and ten inns of chancery, the former being frequented by the sons of the nobility and wealthy gentry, and the latter by merchants and others who had not the means of paying the greater expenses (amounting to about "twenty marks" per annum) of the inns of court. On working days, most of these students, he says, apply themselves to the study of law; and on the holy days to the study of Holy Scripture. But it appears that they did not entirely neglect lighter pursuits, for, says the same learned author, they learn to sing and to exercise themselves in all kind of harmony, and they also practise dancing and other noblemen's pastimes. He says they did everything in peace and amity, and although the only punishment that could be inflicted (as the case is now) was expulsion, they dreaded that more than other criminal offenders fear imprisonment and prisons.

The inns of court, formerly called "hostels," or in French, "hôtel," are Lincoln's Inn, the Inner Temple, the Middle Temple, and Gray's Inn.

Lincoln's Inn appears to have taken its present name from Henry

Lacy, earl of Lincoln, whose house near Holborn had been for some time inhabited by students of law. It has a chapel built by Inigo Jones, the interior of which is very striking, and a noble hall and library, erected in 1846, from the design of Mr. Hardwicke, and recently ornamented by an elaborate and excellent fresco by Mr. Watts. The library contains a very large and well selected collection of books, and a great many very valuable MSS., amongst others those of Sir Matthew Hale. A studentship, worth about 100*l.* a year, to be held for eight years, was founded by Christopher Tancred, Esq., for four students, to be educated in the study of the law at Lincoln's Inn. They are elected by the trustees for the time being of the Tancred Charities. The garden must have been much curtailed since the reigns of Henry VII. and Henry VIII., when, according to Mr. Lane, special enactments were made to prevent the students from hunting the rabbits in it.

The Inner Temple.—This inn, as well as the *Middle Temple*, owes its name to the Knights Templars, who established themselves here about 1185. After their dissolution the Temple came into the hands of "divers professors of the common law that came from Thavyes Inn in Holburne." In the reign of Henry VIII. the members of the Temple had divided into two societies known by the names of the Inner and Middle Temple, each having a hall and a library.

The church is common to both societies. It was founded by the Templars, upon the model of that of the Holy Sepulchre at Jerusalem, and consists of a round tower at the western entrance, and three aisles running east and west, and two cross aisles. In the tower are tombs of eleven of the Knights Templars, but with the exception of one, Geoffry de Magnoville, afterwards earl of Essex, it is not known whom the effigies represent.

Gray's Inn is on the north side of Holborn. It takes its name from the Lords Gray of Wilton.

Each inn of court is governed by its own benchers, or "ancients," as they were formerly called, who fill up the vacancies in their own body, usually selecting queen's counsel, and thus practically vesting the appointment in the Lord Chancellor. At Lincoln's Inn the governing body is called the council, at the Temple the parliament. Their power is undefined, and sometimes assumed to be unlimited. In the two Temples and Gray's Inn, the benchers appropriate to a large proportion of their number, chambers, which they may either occupy or let; so that in this way large sums are often received by the fortunate seniors of the body. See farther, BARRISTER.

Besides these four inns of court, there are eight inns of chancery, which are now only used as chambers, and are principally inhabited by solicitors and attorneys. These are *Furnival's Inn*, *Thavie's Inn*, *Clifford's Inn*, *Clement's Inn*, *New Inn*, *Lyon's Inn*, *Staple Inn*, and *Bernard's Inn*. Several of the inns of chancery have a hall, in some of which dinners are provided and terms kept, but they are now merely private societies.

INOCULATION is the insertion of a morbid fluid formed in the body of one person into that of another. It has however been more particularly applied to the practice of producing small-pox by removing a small quantity of the fluid formed in the pustular eruption on the skin of one person and inserting it beneath that of another. The latter (if he have not already suffered from the disease) will, after the lapse of from seven to ten days, be affected with it; but its severity, when thus engendered, is in a large majority of cases greatly mitigated, so that the proportion of those who die after inoculation is not greater than one in five hundred; while of those who receive the small-pox casually one perishes in every six.

The practice of inoculating for the small-pox was introduced into this country by Lady Mary Wortley Montagu, about the year 1721, her son having thus received the disease during her residence in Constantinople. It had long been practised in Turkey and other Eastern nations, and its utility was well known before its introduction into England, both in the south of Wales and in the Highlands. Mungo Park also found that it was habitually practised by the negroes on the Guinea Coast. It was very slowly adopted in this country, and it was not until it had been practised on six criminals (whose liberty was promised to them if they recovered, as they fortunately did) that it was generally received. It was then almost universally had recourse to, till the introduction of vaccination; but since that time it has most deservedly fallen into disuse. Indeed whatever were the merits of inoculation in lessening the severity of the small-pox in the person inoculated, it was probably on the whole productive of more harm than benefit, by introducing the disease (as it certainly often did) into a district previously free from its contagion; and thus, while it saved the life of one person, it became the cause of the death of many who caught small-pox from him. It is now very rarely practised, and the exposing in public ways or places of persons having the small-pox is punishable. [VACCINATION.]

Of the other eruptive fevers, measles and scarlatina are communicable by inoculation, though with some difficulty and without the advantage of rendering the disease at all milder; but chicken-pox cannot be thus transmitted, and it is at present doubtful whether the exanthematous typhus fever can. Other cases in which diseases are produced by inoculation are treated of in separate articles, as HYDROPHOBIA, &c.

INOCULATION is an operation performed on numerous species of Exogenous plants, and, like grafting [GRAFTING], has for its end the vital union of one species or variety with another. This object may be effected by either of the two operations in the case of many species; but particular circumstances sometimes render inoculation the more proper method, as in the cases of the apricot and peach, which expand their leaves early in the spring, long before growth has commenced in the plum stock, on which they are generally worked. The grafts of such early vegetating trees are generally found to be exhausted before the stocks can contribute a sufficient quantity of fresh organised matter for completing the union. It is therefore found most advantageous to bud or inoculate them in the summer, when both scion and stock are in a state of equal vegetation.

Buds, like grafts, may remain alive for some time after having been inserted on their stock, and may even effect a sort of adhesion to it; but it is only when the alburnum of the two parts, in a nascent state, come in contact, that a permanently vital union is accomplished. Unless this be previously understood, the best instructions with regard to the performance of the operation will be liable to misapplication.

All buds have their origin in the medullary sheath, and are situated in the axils of leaves existing or that have existed; but when a bud has developed itself beyond the external bark, it begins to produce and send down layers of liber, and its connection with the medullary sheath is at that time destroyed. If the bud so detached be placed in favourable circumstances on the alburnum of another allied species, it will derive moisture from the cambium, and continue to vegetate till the granulations of cellular matter resulting from the effort of the stock to cover with fresh matter the part wounded by the introduction of the bud, meet with the alburnum elaborated by the inserted bud; the similar substances then coalesce, and the union may be termed complete. It may be here observed that the opening made for the reception of the bud should not be made too large, for the smaller the portion of bark raised the sooner will it become covered with fresh matter, and meet with that which is forming at the base of the bud.

The season for performing the operation is, generally speaking, from the beginning of July to the middle of August, the particular time varying according to the season. The best criterion is the state of the buds and the degree of cohesion between the bark and alburnum of the stock. If the buds on the young shoots have become so far perfectly formed outside as to bear separation from the branch, and if the bark of the stock can be freely raised, and exhibit an abundance of cambium in a fluid state, the operation may be proceeded with. If, on the contrary, the bark adheres rigidly to the alburnum, or *is set*, as it is technically expressed, there is little chance of success.

In the selection of buds it is necessary to distinguish those that are formed for blossom-buds and those that would produce shoots in the following season. For example, in the case of peach-trees trained against walls, no buds with only a single leaf at their base should be taken, for such, if the tree is in a bearing state, will only produce a blossom, even if it should remain on the tree; and when transferred it will either perish in winter or die after an imperfect development. On vigorous young trees in the open ground that are not in a blossoming state single *wood-buds* may be readily found, and they are preferable to all others. When a bud on a wall has two leaves at its base it will produce from thence one *wood-shoot* and a blossom-bud; in fact, although only one bud is apparent, yet there exist two; since every leaf has in its axil either a bud or the rudiments of one. Thus a shoot having buds with three leaves at their bases developes itself in the following spring, in the form of two blossom-buds and a wood-bud in the centre.

The operation of budding, or inoculation, is performed in various ways; but the best and most general is that called shield-budding or T budding, from the resemblance of the two cuts made in the bark of the stock to the two principal bars of the Roman letter T. In a smooth part of the stock a horizontal cut is made through the rind down to the alburnum; but care is taken that the incision only just reaches the alburnum. From the middle of this another cut is made downwards. The bud is then shaved off the shoot by entering the knife about half an inch below it, then cutting nearly half way through the branch immediately below where the bud is seated, and finally by slanting the knife outwards about half an inch above the bud. A portion of bark and young wood will thus be taken along with the bud; but the wood must be carefully separated by being dexterously jerked off *downwards* in the direction of the woody fibre, leaving only the small portion belonging to the base of the bud. If the wood were detached by pulling upwards, this minute formation of alburnum belonging to the bud would likewise be removed, and with it the *root*, as it is called, of the bud, or vital speck. This will sometimes happen, whichever way the wood is removed, and may be known by the appearance of a small hole below the external convexity of the bud. When this happens the operation must be repeated. The bud being thus prepared and its bark pared so as to be easily introduced below that of the stock, and as much reduced as its immediate connection with the bud will permit, the bark of the stock is raised with the thin flat ivory handle of the budding knife by entering it at the angles formed by the transverse and perpendicular incisions above described, taking care not to disturb the bed of cambium; on the latter the bud, with its shield-like portion of bark, is placed, its upper part being then cut off, so as to coincide with the transverse section on the bark of the stock; the lips of the perpendicular incision are closed, or at least brought down upon the shield of the bud; and the whole is bound down with a strip of pliable matting, the point of the bud only being missed by the bandage. The latter must be untied and slightly re-tied when the swelling of the stock indicates the necessity of the operation.

INOSIC ACID ($C_{10}H_7N_2O_{11},HO$?). This acid is a constituent of the juice of meat. It is best prepared from the flesh of the common fowl. Fresh lean of fowl is to be finely chopped and digested in its own weight of water; the filtered liquid heated nearly but not quite to the boiling point, to coagulate albumen; baryta water added to separate phosphoric acid, and the filtrate then evaporated till of the consistence of thick syrup: it is now diluted with alcohol till it becomes milky, and set aside. After a time crystals appear, which are inosate of potash, and of baryta, if excess of the latter base has been used. The crystals are redissolved in warm water, and chloride of barium added. On the cooling of the solution, inosate of baryta crystallises out, and requires only another crystallisation to be obtained perfectly pure. This salt has the composition ($BaO, C_{10}H_7N_2O_{11} + 6Aq$).

Inosic acid may be isolated from the baryta salt by the cautious addition of sulphuric acid. Its dilute solution in water has a very acid reaction, and an agreeable taste, resembling juice of meat. It may be concentrated, by a heat not exceeding 140° Fahr., to the consistence of syrup, but cannot be made to crystallise. It is insoluble in alcohol or ether. The name inosic acid was given to this body by Liebig, its source being thereby indicated (*ἴς, ἰνός*, muscle).

INOSITE ($C_{12}H_{12}O_{12} + 4HO$) is a peculiar species of sugar, discovered by Scherer in the juices obtained from the flesh of animals. It crystallises in large crystals, which have a sweet taste, but which are not susceptible of vinous fermentation. It yields, however, both lactic and butyric acids when exposed to the action of casein. It differs from glucose in its not giving the usual reaction with the salts of copper and potash, and in possessing two atoms more water in its composition.

The following is the characteristic reaction for inosite: the solution suspected to contain this body is evaporated to dryness on platinum foil with nitric acid, then the residue is moistened with ammonia and a little chloride of calcium added, finally on evaporating again to dryness the residue becomes of a beautiful rose colour. Neither starch nor any of the sugars produce this reaction, which is so delicate as to admit of the detection of less than the $\frac{1}{100}$th part of a grain of inosite.

INQUEST. [CORONER.]

INQUISITION, THE, of which the more correct title is the Holy Office (*Sanctum Officium*), is the name of an ecclesiastical tribunal established in the 13th century by popes Honorius III., Gregory IX., and Innocent IV., to try heretics, blasphemers, apostates, relapsed Jews or Mohammedans, witches and wizards, polygamists, and other persons charged with infractions of the canons of the Church. The judges of this court were called inquisitors, whence the tribunal itself has been commonly styled the "Holy Inquisition." The name of inquisitors, or inquirers after heretics, appears as early as the reign of Theodosius I., who, by his constitution against the Manichæans and other heretics, A.D. 382, after adjudging the punishment of death for several aggravated cases of heresy, directs that "Inquisitores and conquirendos et eruendos hereticos" be appointed by the prefect of the Prætorium. ('Codex Theodosianus,' Gothofredi, xvi., tit. 5, lex 9.) This is the first law under the Christian emperors by which the punishment of death is awarded for heresy. Constantine had only sentenced the Arians to banishment, though he threatened to punish with death those who should retain and make use of the books of Arius. The subsequent law of Honorius, A.D. 398, expels from the towns the "Clerici" or priests of the Montanists and Eunomians, and if they persist in bringing people together, it banishes them for life. It further orders their books to be burnt, and condemns all persons who are found to conceal them to be beheaded. ('Cod. Theod.' xvi., tit. 5. l. 34.) Two more constitutions or laws of Honorius (51 and 56 of the same book and title in the Theodosian Code) threaten with proscription and death those who publicly profess certain heresies. These are the oldest laws on record which make heresy a capital crime; but it ought to be observed, that there is no law in the whole Theodosian Code which subjects heretics in general to the pain of death, that punishment being reserved for the leaders, those who collected assemblages of people, made proselytes, and preached or spread certain heterodox doctrines specified and condemned by the laws. The trial and punishment in all such cases were left to the civil magistrate.

Previous to the time of Theodosius I. there had been persecutions of Arians by the Orthodox, and *vice versâ*, carried on through the violence of individuals; but there was no specific law making heresy a capital offence. Towards the heathens the case was different. Constantius (A.D. 353) had forbidden heathen sacrifices under pain of death. Theodosius I. confirmed that law, and Theodosius II., after remitting the capital penalty (A.D. 423), put it in force again in 426. (Gothofredus, 'De Statu Paganorum.') Most of the earlier fathers, Tertullian, Cyprian, Lactantius, Hilarius, Ambrose, and Gregory Nazianzenus, and even Athanasius, openly disclaim violence as a means of enforcing unity and obedience to the Church. Chrysostom and Augustine however think that heretics ought to be prevented from holding assemblies, and ought to be confined or banished, but not put to death. But it ought to be remembered that the heretics of those times, the Arians and Donatists in particular, constituted political factions which rebelled against the authority of the state, murdered their antagonists, demolished their houses, and committed all sorts of violence, as may be seen by the letters of Augustine.

The first person on record who was juridically condemned and put to death for heresy is Priscillianus, the leader of a sect in Spain, in the latter part of the 4th century. Two Spanish bishops, one of whom was called Idacius, accused Priscillianus, with two other priests or bishops, before a council held at Bordeaux, A.D. 385. Priscillianus appealed to the emperor Maximus, who had assumed the imperial purple in Gaul, and who was then residing at Treves, whither Priscillianus and his friends were taken, being followed by their prosecutor Idacius. Martin, bishop of Tours, interceded in their behalf; but after his departure from Treves, Maximus entrusted Evodius, the prefect of the Prætorium, with the trial of the accused, and upon his report Maximus condemned them to be beheaded. This novelty was generally censured, and Ambrose and Martin of Tours strongly reprobated the part which Idacius had acted, and which they characterised as unbecoming the episcopal character. The consequence was, that Idacius was excommunicated, and died in exile.

Justinian, in the first book of his Code, in which he treats of the Catholic faith, and defines its creed according to the first four general councils, of Nicæa, Constantinople, Ephesus, and Calchedon, forbids public disputations upon dogmas, and enacts several penalties against heretics, Jews, and apostates. In the 131st Novel, the same emperor says: "We receive the doctrines of the four Holy Synods as the Divine Scriptures, and their Canons we observe as laws." Thus the orthodox creed, as expounded in the four councils, became the law of the empire, an empire which was then administered despotically, and dissent from that creed was an offence against the law. From this principle the whole penal code against heretics was derived. But for several centuries after, cases of heresy were tried and penalties awarded by the ordinary courts, as the bishops had not then any temporal jurisdiction. In course of time however councils interfered, and after condemning particular tenets as heretical, specified in some instances the punishments to be inflicted upon heretics, Jews, and apostates. [JEWS.] It became the practice for the bishops to examine the accused, and decide whether there were sufficient grounds for the charge of heresy against them; if the charge was proved, they were to admonish them, and convince them of their errors, after which, if the accused remained obdurate, the bishop handed them over to the secular court. "Heretici perseverantes in errore relinquantur Curiæ secularis judicio." (Council of Tarracona, A.D. 1242.) And the law of Las Partidas, which is still the fundamental code of Spain, promulgated in 1258, says: "Heretics may be accused by any one of the people before the respective bishop or his vicar, who must examine and interrogate them upon the various articles of the faith, and if they find that they err in them or in any other thing which the church of Rome commands to be believed and observed, he must endeavour to convert them and make them forsake their errors by means of good arguments and mild words. And when the penitents have acknowledged their belief, they are to be reconciled to the church and be forgiven. But if it so happens that they will not forsake their errors, the bishop must convict them as heretics, and then hand them over to the secular or lay judges." The lay judges however were not mere executors of the episcopal verdict: they examined the proceedings, and having convinced themselves of their regularity, they awarded the penalty. By a clause of the same law of Las Partidas, "the property of those who are condemned as heretics, or who die in the heretical belief, belongs to their children or other descendants." The principle of confiscation is here not recognised. This was in the kingdom of Castile; but in Aragon, France, and Italy, a different process was introduced by means of the Inquisition.

In the Council of the Lateran, convoked at Rome in 1215, by Innocent III., new and severe enactments were made against heretics, but the cognisance of matters of heresy was left to the ordinaries or bishops. But some years before this time, Innocent himself, of his own authority, had sent a commission consisting of two legates, who were Cistercian monks, accompanied by subordinate priests and officers, to the south of France, in order to extirpate the heresy of the Albigenses. These legates acted independently of the local bishops; they held their own court, before which they summoned, by the authority of the pope, individuals accused of heresy, and condemned, and inflicted penalties, and even capital punishments. Dominic de Guzman, the founder of the order of Dominicans, was one of the most zealous agents of this commission, the members of which were called Inquisitors. This however was only a temporary and local commission.

In 1208, Peter de Castelnau, one of the legates, who had become obnoxious for his severity, was murdered near Toulouse, and Innocent was so exasperated, that he preached a crusade against the Albigenses, which, after a long struggle, ended in their extermination. [ALBIGENSES.] Honorius III., the successor of Innocent, issued new provisions against heretics, which were enforced by the emperor Frederic II. in three constitutions, or laws, dated Pavia, 1224, by which he condemned impenitent heretics to death, and those who repented to perpetual imprisonment. In the year 1228 a severe penal law against heretics was enacted in the city of Milan by Cardinal Godfrey of St. Mark, papal legate, with the consent of the archbishop and the people; it was to the effect that "no heretic should be allowed to remain in the state of Milan; that any person might lay hands on a heretic and bring him before the magistrates; that those who were convicted as heretics by the Ecclesiastical Court should be executed by the prætor within ten days, their houses pulled down, and their property confiscated to the community." (Calchi, 'Historiæ Patriæ,' b. xiii.; Corio, 'Storia di Milano,' part ii., p. 72; Verri, 'Storia di Milano,' ch. ix.) No less than fifteen sects of heretics, with strange names, are enumerated by these historians as having been discovered within the state of Milan. The archbishop of Milan at the time was Enrico da Settala, who exerted himself greatly in rooting out the heretics, and having probably exceeded all bounds, he was at last banished by the council of the republic, for which the council and the podestá were excommunicated by the pope. In the inscription on the tomb of this archbishop, it was stated that "being appointed inquisitor, he destroyed the heretics." It was about the year 1233 that Pope Gregory IX. laid down the rules and defined the jurisdiction of the inquisitors courts, which he sent to various countries, under the name of Inquisitorial Missions. He appointed as chief inquisitor in Lombardy, Pietro da Verona, a Dominican monk, who was strenuously seconded by the then podestá of Milan, Oldrado da Tresseno, who consigned to the flames numerous heretics. The likeness of this podestá was, not many years since, and probably is still, seen sculptured in relief in the façade of the hall of the municipal council at Milan, with an inscription recording, among other things, that he had burnt the heretics as in duty bound: "Catharos, ut debuit, uxit." The chronicler Fiamma says, that he was the first who put heretics to death in Milan. By degrees inquisitors were sent by the popes to most Italian cities and states, where, with the consent of the local authorities, they established their tribunal, and had their officers, notaries, informers, and other agents. Dominican monks were generally employed as inquisitors, as the principal object of the institution of their order was to defend the orthodox faith by arguing and preaching against heresy, on which account they are styled "Fratres Prædicatores," or brother preachers. The inquisitor Pietro da Verona, in the course of nineteen years, burnt a great number of heretics throughout Lombardy, banished or frightened away a still greater number, and confiscated their property. A certain Confaloniere of Alliate, being warned that he was on Fra Pietro's list, conspired with several of his friends, who lay in wait for the inquisitor, and on the 6th of April, 1252, as he was returning from Como to Milan, in company with another Dominican, they killed him near Barlassina, and wounded his companion, who died a few days after. The inquisitor was shortly after canonized by Pope Innocent IV., under the title of St. Peter Martyr. In 1277, another Dominican, brother Pagano da Lecco, was killed in the same manner in Valtellina.

The chroniclers of the various cities of Lombardy record the acts of the inquisitors, and the number of heretics and witches whom they put to death at particular times. The chronicle of Muralto states that brother Antonio da Casale, inquisitor of Como, in 1416, sent three hundred heretics to the stake in one single year. Tartarotti states that in the year 1485 forty-one witches were burned at Como. Bartolomeo Spina, 'De Strigibus,' ch. 13, states that in the diocese of Como the number of those who were tried annually by the Inquisition exceeded one thousand; that the inquisitor employed eight, ten, and even more vicars, and that almost every year about one hundred persons were burned. ('Lettere del Conte Gianbattista Giovio all' Abate Bettinelli,' letter vi.)

The Inquisition was introduced into Rome as well as other parts of Italy by Gregory IX., and entrusted to the Dominicans, but it was a long time before it was established as a distinct and permanent court. Inquisitors were appointed by the pope on particular occasions, who visited the various provinces and towns, proclaiming to all persons the obligation they were under of informing against those whom they knew or suspected of being heretics, under pain of excommunication. At the same time they also made it known that all persons guilty of heresy who came of themselves before the inquisitor within a certain fixed period, and accused themselves and professed repentance, should receive absolution and be only subject to a canonical penance. These penances were public, humiliating, and very severe, as may be seen by a letter of St. Dominic concerning a heretic whom he had converted, by the acts of the council of Béziers, in 1233, and of the council of Tarracona in 1242. After the expiration of the period of grace, the inquisitor proceeded *ex-officio* against those who were denounced, the name of the informer being kept secret: he examined witnesses privately in presence of a notary and two priests, and having taken down the evidence in writing, he read it over to the witnesses, who were asked whether they confirmed what had been read. If there appeared to be sufficient grounds for proceeding against the accused, the inquisitor ordered his arrest by the municipal officers, and he was taken to the convent of the Dominicans, if there was one in the town, or to the prison of the ecclesiastical court. He was then interrogated by the inquisitor, and his answers might be used afterwards as evidence against him. If the accused denied the charge of heresy, he was supplied with a copy of the instruction and depositions, but without the names of the accuser and witnesses, and with the omission of such circumstances as might discover them. The accused having made his answer or defence, which was taken down in writing, if he denied the charges, the inquisitor, together with the bishop of the diocese or his delegate, if they thought proper, ordered him to be put to the torture in order to obtain his confession. The torture might be repeated three times, but it was afterwards ordered to be applied only once; this regulation, however, was often evaded by suspending the torments and then resuming them, and considering the whole as one torture. If in the end there were not sufficient grounds for the conviction of the prisoner, he was declared to be "suspected of heresy," was obliged to make a public abjuration of all heresies, and was subject to certain penalties, according to the nature of the case. If the accused was convicted of heresy, but professed his repentance, he was condemned to prison for life—a penalty which, however, might be mitigated by the inquisitor. But if he was a *relapsed*,—that is to say, had been tried before, and found guilty or only strongly suspected,—there was no mercy for him: he was "relaxatus;" that is to say, given over to the lay magistrate, who, according to the civil and canon laws, was bound to put him to death upon the sentence of the inquisitor which declared him a heretic. The only favour shown to the relapsed heretic who confessed and abjured his guilt was, to be strangled before he was burnt. If the convicted heretic was not relapsed, but impenitent, a respite of the sentence was granted in order to effect his conversion, and if he at last abjured his life was spared, and he was sentenced to perpetual imprisonment. If he persisted in his impenitence, he was publicly burned alive. Such were the principal characteristics of the old or delegated Inquisition as it existed from the 13th century to the latter part of the 15th, and the regulations of which are found in the 'Directorium Inquisitorum' of Friar Nicholas Eymeric, a native of Catalonia, and a Dominican monk of the 14th century, who held the office of chief inquisitor in Aragon for 42 years.

The Inquisition had nearly fallen into disuse in the kingdom of Aragon in the 15th century, in consequence of the total extinction of the heretical sects in the south of France, whose spreading on the other side of the Pyrenees had occasioned the introduction of the inquisitional courts into Catalonia and Aragon. In the kingdoms of Castile and Leon, and of Portugal, the Inquisition had not yet taken permanent root. But towards the end of the 15th century the Holy Office was introduced into Spain under a new and more appalling form, and became consolidated and permanent, and more absolute and independent than in any other country of Europe. This is what is designated by Llorente and other writers by the name of the 'Modern or Spanish Inquisition.'

Alfonso de Hodeja, prior of the Dominican convent of Seville, and Friar Philip de Barberis, inquisitor of the kingdom of Sicily, which was then subject to the crown of Aragon, suggested to Ferdinand and Isabella, in 1477, the establishment of the Inquisition in Spain for the purpose of punishing those Christians who secretly relapsed to the Jewish faith. The converts, or children of converts, from Judaism, were looked upon with dislike and mistrust by the old Christians; and many of them were at the same time among the wealthiest merchants and monied men of Spain, and as such had numerous debtors. Reports were spread of their secret meetings with those who had remained Jews, of their profaning the images of Jesus Christ, and even crucifying Christian children. Ferdinand easily listened to the suggestion; but Isabella, a princess of mild character, hesitated for some time, and without her consent nothing could be effected in the dominions of the crown of Castile. Means were at last found to alarm her conscience; she was told that the interests of religion required her acquiescence, and accordingly she solicited, by means of her ambassador at Rome, a papal bull, authorising the establishment of the Inquisition in the kingdom of Castile. The bull, despatched from Rome in November, 1478, authorised Ferdinand and Isabella to appoint two or three bishops or other dignitaries of the Church, aged at least forty years, of irreproachable character, graduates in theology and the canon law, who were to be commissioned to seek after and discover, throughout the dominions of the Spanish sovereigns, all apostates, heretics, and their abettors, with full power to proceed against them according to law and custom. Isabella, however, suspended the execution of the bull for two years, desiring at the same time that measures of persuasion should be adopted to warn the relapsed converts of their error and of their danger. A catechism was composed expressly for them, and several pamphlets against Judaism were issued. In 1480 the Cortes of Castile assembled at Toledo, and passed several restrictive measures against the Jews, with the view of checking their intercourse with the Christians. Nothing, however, was said in that assembly about the Inquisition. At last, in September, 1480, Ferdinand and Isabella, who were then staying at Medina del Campo, appointed two Dominicans as inquisitors, with an assessor and a fiscal attorney; and on the 9th of October a royal order was despatched to the governors of provinces to furnish the new inquisitors and their retinue with everything necessary for their journey to Seville; and at the same time their privileges were declared, which were the same as those granted by the Emperor Frederic II. to the inquisitors in Italy in the 13th century. The inquisitors established their court in the Dominican convent of St. Paul of Seville, whence, on the 2nd of January, 1481, they issued their first edict, by which they ordered the arrest of several "new Christians," as they were styled, who were strongly suspected of heresy, and the sequestration of their property, denouncing the pain of excommunication against those who favoured or abetted them. The number of prisoners soon became so great that, the Dominican convent not being large enough to contain them, the court was removed to the castle of Triana, in a suburb of Seville. The inquisitors issued another edict, by which they ordered every person, under pain of mortal sin and excommunication, to inform against those who had relapsed into the Jewish faith or rites, or who gave reason for suspecting them of being relapsed, specifying numerous indications by which they might be known. Sentences of death soon followed; and in the course of that year (1481) 298 new Christians were burnt alive in the city of Seville, 2000 in other parts of Andalusia, and 17,000 were subjected to various penalties. The property of those who were executed, which was considerable, was confiscated. (Mariana, 'Hist. de España,' b. 24, ch. 17.) The terror excited by these executions caused a vast number of new Christians to emigrate; several who were condemned as contumacious repaired to Rome, and appealed to Pope Sixtus IV. against the inquisitors. The pope wrote to Ferdinand and Isabella, in January, 1482, complaining of the arbitrary conduct of the two inquisitors appointed by them, revoking the authority which he had given to their majesties to appoint other inquisitors, and reserving that right to himself, which he exercised by a brief in the following February. Among these new appointments was that of the afterwards famous Torquemada. Queen Isabella now wrote to the pope, requesting him to give a permanent and fixed form to the new tribunal, and to make its judgment definite without appeal to Rome, complaining at the same time that she was accused of doing all that she had done in favour of the Catholic faith for the sake of the confiscations which follow the condemnations. The pope laid the proposal of Isabella before a committee of Spanish cardinals and bishops who were then at Rome, and among whom was Rodrigo de Borja, afterwards Pope Alexander VI. By their advice, Sixtus IV. despatched a brief to Isabella, appointing Manrique, archbishop of Seville, to be apostolic judge of appeal for all Spain, with power to decide on all appeals from the judgments of the Inquisition. By several other briefs, directed to the various archbishops of Spain, the pope gave them the power and regulated the manner of appointing the ordinary inquisitors in the various dioceses. Notwithstanding these measures, appeals from Spain continued to be received at Rome; and the pope again wrote, in August of the same year, to the Archbishop of Seville, ordering the proceedings against several individuals to be quashed, and recommending mildness and moderation. This recommendation however had no effect. Soon after, the pope appointed Thomas de Torquemada, prior of the Dominican convent of Segovia, to the new dignity of inquisitor-general of the kingdom of Castile; and by another brief, dated 17th October, 1483, he made him likewise inquisitor-general of the kingdom of Aragon, with full jurisdiction over all other inquisitors in Spain and its dependencies. His powers were confirmed by Innocent VIII., in February, 1486. Torquemada chose for his assessors and councillors two jurists, J. Gutierrez and Tristan de Medina: he created four subordinate courts, at Seville, Cordoba, Jaen, and Villa Real; the last was soon after transferred to Toledo. The Dominican monks, who had been appointed inquisitors by the pope in February, 1482, at first refused to submit to the authority of Torquemada, but they finally yielded. Ferdinand at the same time appointed a royal council of the supreme Inquisition, "Consejo de la Suprema Inquisicion,' of which the grand-inquisitor was president of right and for life, and a bishop and two doctors-at-law were councillors. The councillors had a deliberative vote in all matters of civil law, but the president alone judged in matters which concerned the canon or ecclesiastical law.

Torquemada and his two assessors framed the organic laws of the new tribunal, which were styled 'Instructions,' and were partly based on the older 'Directorium Inquisitorum' of Eymeric. Being sanctioned by a junta of the inquisitors of the four courts which he had established and of the royal councillors, the instructions, consisting of 28 articles, were promulgated at Seville, the 29th October, 1484. They are given at length by Llorente, in the sixth chapter of his History. New articles were added to them in 1488 and 1498; and, lastly, the inquisitor-general Valdez, in 1561, compiled a new series of ordinances in 81 articles, which regulated ever after the practice and proceedings of the Spanish Inquisition. They are also given by Llorente, in the 22nd chapter of his work. They are substantially the same as those already noticed as being in practice by the old Inquisition, but are more minute, and rather more unfavourable to the accused. By the old practice, for instance, the names of the witnesses for the prosecution were in many cases communicated to the accused, to whom they were of great use for his defence. Confiscation of the property of those who were condemned was not generally enforced under the old practice, and this was more particularly the case in the kingdom of Aragon, a circumstance which explains the resistance of the Aragonese, among whom the old or delegate Inquisition had been established for centuries, to the introduction of the new Inquisition as instituted by Torquemada.

Another important characteristic of the new Spanish Inquisition was its compact organisation and independence of all other authorities. The inquisitor-general was appointed for life; he was proposed by the king and approved by the pope. He appointed all other inquisitors under him, as well as visitors and other agents. He had full and discretionary power by the papal bulls in all matters of heresy. The grand-inquisitor, being thus placed as a distinct power between the king and the pope, was in reality independent of both. He could refuse to submit to those papal decretals and bulls which he did not approve, by alleging that they infringed upon the rights of the Spanish monarchy; and he could likewise evade the king's ordinances, by alleging the papal bulls which forbade the inquisitors to tamper with the secular power under pain of excommunication. Among other proofs of this assumed irresponsibility, one of the strongest is the famous trial of Carranza, archbishop of Toledo, in the reign of Philip II., who had attended Charles V. at St. Yusto in his last moments, and whom neither the briefs of the pope Pius IV., nor the remonstrances of the prelates assembled at the council of Trent could save from being confined in the prisons of the Spanish Inquisition for more than seven years, without a termination of his trial; and when at last pope Pius V. demanded of the Spanish inquisitor and of the king, under pain of excommunication, that the archbishop and the papers of his trial should be sent to Rome, all sorts of obstacles were thrown in the way of his departure and his final acquittal by the pope. After the death of Pius V. new proceedings were commenced in Spain to prove the archbishop guilty of heresy, and on the information being transmitted to Rome, Gregory XIII., who had succeeded Pius V., was, though with evident reluctance, induced to declare, on the 14th April, 1576, that the archbishop of Toledo was strongly suspected of believing sixteen propositions qualified as Lutheran, and which had been deduced from the context of his writings by the casuists of the Inquisition. He was then sentenced to five years' confinement in a Dominican convent and other canonical penances. A few days after this sentence, the archbishop, who was then seventy-two years of age, was taken dangerously ill, and before receiving the sacrament, on the 30th of April, he solemnly declared in presence of several witnesses "that he had never fallen into the errors with which he had been charged; that his expressions had been distorted into a meaning totally different from his; that he however humbly submitted to the judgment pronounced by the sovereign pontiff, and heartily forgave all those who had taken part against him in the trial, and would pray for them before the throne of Grace." On the 2nd of the following May the archbishop died in the convent of La Minerva at Rome, in which he was detained, and where he was buried. An inscription was placed over his tomb by order of Gregory XIII., in which he was described as a prelate "illustrious for his birth, his life, his doctrine, his preaching, and his charity." Llorente gives a copious abstract of this celebrated trial in chapters 32, 33, and 34 of his 'History of the Inquisition.'

Pope Paul III., alarmed at the progress of the doctrines of the Reformation, with the consent of Charles V. sent inquisitorial commissioners to the various states and provinces of Italy to try heretics; but they were instructed to proceed according to the usual form of the ecclesiastical courts, the depositions and names of the witnesses were to be communicated to the accused, and sentence of condemnation was not accompanied by confiscation; in short their powers were very different from those of the Spanish Inquisition. The Spanish viceroy of Naples, Don Pedro de Toledo, applied to the pope for an inquisitorial commissioner with a brief to proceed against persons suspected of heresy, but the Neapolitans, who were acquainted with the severities of the Spanish Inquisition, revolted, and, after much bloodshed, Charles V. promised that no Inquisition should be established in the kingdom of Naples, and that cases of heresy should be tried, as before, by the ordinary episcopal courts. These occurrences took place in 1546-7, and the Neapolitans, the better to secure themselves against the dreaded tribunal, established a court whose office it was to watch against any attempt to introduce the same under any shape—a kind of inquisition against the Inquisition. This court, which continued to exist till the French invasion of 1799, was styled "Tribunale contro quello del Sant Uffizio," and was composed of deputies, chiefly noblemen chosen by the different Seggi into which the Neapolitan nobility was classed. To the Neapolitan character, mercurial and communicative, the secret and mysterious proceedings of the Inquisition were peculiarly obnoxious.

Philip II. wished to introduce the Spanish Inquisition into the duchy of Milan, but the towns of Lombardy sent deputies to the council of Trent to remonstrate against it, and the Milanese and other Italian bishops wrote to the pope and to Cardinal Borromeo, representing that the Inquisition of Spain acted in the dark, in an arbitrary manner, and with strange and fearful forms of proceeding, that it took away the jurisdiction from the bishops, that it showed itself more a rival than a subject to the papal see, that it had repeatedly refused to send a copy of its trials to Rome, and that if it were introduced into Italy, the Italian prelates, having its terrors before their eyes, would become estranged from the holy see. The pope, being easily persuaded by these reasons, interposed with King Philip, saying that if required he would, after consulting with the bishops of Lombardy, himself send inquisitorial commissioners from Rome, who should proceed not according to the Spanish form, but according to the canon law, and without prejudice to the episcopal authority. Thus the Spanish Inquisition was not introduced into Milan or into any other Italian state, with the exception of Sicily, which was an old dependency of the crown of Aragon.

The court of the Inquisition, as it was established in the 16th century, in Tuscany, Venice, Milan, Parma, and other Italian states, consisted of one inquisitor, sent from Rome, with assessors approved by the sovereign of the respective states, who appointed deputies or commissioners to attend the trials and report to him. The sentences of the court were subject to the sanction of the temporal sovereign.

The republic of Venice showed itself the most jealous of its sovereign rights in this particular. A series of statutes were issued at various times by the senate to regulate the proceedings of the inquisitors, which are given by Paolo Sarpi, in his 'History of the Venetian Inquisition,' and by Limborch, b. i., ch. 17. By a concordat with Pope Julius III., 1551, it was decreed that three senators were to attend all the proceedings and judgments of the Inquisition in the city of Venice, and although they took no part in the trial, they had the right to suspend the execution of the sentence and report to the senate. In the provincial towns lay magistrates were appointed to perform the same duty in the respective courts of the Inquisition. The Inquisition could not molest Jews or other unbelievers, or Greeks living under the protection of the republic. It could not take cognisance of cases of blasphemy or polygamy—which belonged to the secular jurisdiction—nor of witchcraft, nor of minor infractions of discipline, such as eating or selling of meat on Fridays, &c. Numerous other checks are provided by the same statutes. In short, although the Venetian senate was obliged by prudential reasons to admit the Inquisition within its territories, it took care to render it as inoffensive as possible. The famous tribunal of the state Inquisition, was entirely a political institution of the Venetian aristocracy, and must not be confounded with the ecclesiastical Inquisition.

In Tuscany the grand-dukes Medici had provided that deputies appointed by themselves should attend the trials of the inquisitorial court, and should report to them, and that no sentence should be executed without their sanction. But in the year 1566, Pope Pius V., a zealous promoter of the Inquisition, demanded of the Grand-duke Cosmo I. the person of Pietro Carnesecchi, a man of some rank and learning, and well affected to his sovereign, but who had publicly adopted several tenets of the Protestant Reformers. Cosmo gave him up to the officers of Rome, but at the same time wrote earnestly to the pope to save him. Pius was inclined to spare his life, if Carnesecchi had shown signs of repentance, but he boldly persisted in his opinions, and in August, 1567, he was convicted by the Roman Inquisition of thirty-four heretical tenets, and condemned to death. The grand-duke again wrote in his behalf, and the pope suspended the execution for ten days, promising to spare his life on condition that Carnesecchi should abjure his tenets, and he sent him a friar to exhort him to do so. But Carnesecchi remained firm: he argued with the monk, and wanted to gain him over to his own opinions. He was publicly beheaded at Rome, and afterwards burnt. In the following century Galileo was summoned from Florence to Rome, where, however, he was treated with considerable lenity, and after a verbal abjuration and a few months' confinement, he was allowed to return to Florence. The executions in Tuscany in consequence of sentences of the Inquisition were comparatively few. The tribunal continued to exist in Tuscany till the reign of Leopold of Austria, who began by curtailing its jurisdiction, took away its "sbirri," or bailiffs, gave the censorship of books to a lay magistrate, and at last abolished the tribunal altogether in 1787. About the same time it was suppressed at Milan by the Emperor Joseph II. In 1769 the Duke of Parma abolished it in his territories.

Pope Paul III. founded at Rome, by a bull dated April, 1543, the Congregation of the Holy Office, consisting of six cardinals, who were styled "inquisitors-general of the faith," who had the superintendance over all other inquisitors, and he gave them full authority to proceed, without the concurrence of the ordinaries or bishops, against all heretics or persons suspected of heresy, to punish them, confiscate their property, to degrade and deliver to the secular courts all clerical offenders, to call in if required the assistance of the secular arm, to appoint inquisitors with such powers as they thought proper, to appoint fiscal attorneys, notaries, and other officials, and to hear and decide on appeals from the judgment of other inquisitors. The pope, however, declared that by this bull he did not intend to make any alteration in the privileges of the Spanish Inquisition as then established.

In 1564 Pope Pius IV. confirmed and extended the powers of the Roman Inquisition, which, however, were resisted in the kingdom of France. In that kingdom there was no regular tribunal of the Inquisition. The Cardinal de Lorraine, under Henri II., had indeed appointed delegated inquisitors who acted as extraordinary judges in the trials of the Huguenots, but their jurisdiction was not exclusive, as the parliament also took cognisance of the crime of heresy, besides which the king appointed special commissioners for the same purpose. ('Histoire du Parlement de Paris,' ch. 21.) But the authority of the Inquisition was totally abolished in France as soon as tolerance was established by the Edit de Nantes under Henri IV., which allowed the Protestants the exercise of their religion, for tolerance and the Inquisition could not possibly exist together; and although Louis XIV. afterwards revoked that edict and persecuted the Protestants, he did it by means of the secular power, and took care not to allow the introduction into his kingdom of an ecclesiastical tribunal which would encroach upon his own sovereign authority. But he advised his grandson Philip V., whom he placed on the throne of Spain, to maintain the Inquisition as a means of ensuring the tranquillity of that kingdom.

Sixtus V. in 1588, having distributed the cardinals into fifteen congregations or boards, made that which was styled "Holy Roman and Universal Inquisition" to consist of twelve cardinals with several prelates as assessors, including the Master of the sacred palace, several monks with the title of "consultors," besides other clergymen and lawyers called "qualificators," whose business it was to prepare the cases. This is the Inquisition which still subsists at Rome, but its jurisdiction does not extend beyond the limits of the Papal States, and it is generally understood that its powers are exercised with considerable leniency and caution. Pius VII., after his restoration, is said to have abolished the use of the torture. The Roman Inquisition watches more particularly over the conduct of the clergy, and has also the censorship of the press and of the introduction of foreign works. The territory subject to the dominion of the pope is now the only country in which the tribunal of the Holy Office still remains.

In Germany and in Poland, the Inquisition has long since ceased to exist. In Spain it was suppressed, first by a decree of Napoleon, dated Chamartin, 4 December, 1808, as encroaching upon the rights of the sovereign, "attentoire à la souveraineté;" and on the 12th February, 1813, the extraordinary Cortes of Spain assembled at Cadiz definitively suppressed the Inquisition, as being incompatible with the new political constitution of the monarchy. At the same time they restored to the bishops the exercise of the ecclesiastical jurisdiction in cases of heresy. Ferdinand VII., after his restoration, re-established the Inquisition by an ordinance of the 21st July, 1814, and appointed the bishop of Almeria inquisitor-general. In this act Ferdinand stated to the people that one of his objects in re-establishing the Inquisition was "to repress the mischief occasioned to the national faith by the presence of the foreign troops which were not Catholic," including of course his allies the English, who had been the chief means of restoring him to the throne. It continued in Spain till the Revolution of 1820, when it was again suppressed by the Cortes. During these five years of its re-establishment, many persons were arrested, but none appear to have been put to death in consequence of its judgments. When Ferdinand, in 1823, a second time overthrew the constitution, he did not re-establish the Inquisition. In Portugal, the Inquisition, which was likewise abolished by the Cortes, has not been restored.

Various and often exaggerated accounts have been published of the number of persons put to death by the Spanish Inquisition during the three centuries of its existence. Llorente, who wrote with calmness and had access to the archives of the tribunal, gives an approximate estimate of the number executed under each inquisitor-general, from which it results that the total amount in Spain is about 32,000 persons burnt, either alive or after being strangled, 17,000 burnt in effigy, and 291,000 condemned to various terms of imprisonment, to the galleys, or subjected to other penalties. During the eighteen years of Torquemada's inquisitorship alone, about 8800 persons were burnt. This calculation does not include the Spanish colonies, nor the islands of Sicily and Sardinia, which were long subject to the Spanish Inquisition. It is impossible to ascertain the amount of the victims of the Inquisition in these as well as in other countries of Europe. The last person burnt by the sentence of the Inquisition in Spain was a woman accused of having formed a contract with the devil. She was burnt at Seville, on the 7th of November, 1781. The three last inquisitors-general, from 1783 to 1808, did not sentence any one to death.

In examining the history of the Inquisition under its various forms two things ought to be carefully distinguished; the principle and the practice of that remarkable institution. The fundamental principle of the Inquisition is, that heresy, that is to say, dissent from the tenets of the Roman church, is a heinous crime, and liable to both spiritual and temporal punishment. This principle however is not peculiar to the Inquisition: it is that of the canon law, and it has the countenance of the Roman law in several constitutions of the early Christian emperors. In every country therefore in which the canon law has civil or temporal force, the principle subsists, although it may lie dormant. A subject of such a country who should openly dissent from the established Church is liable to prosecution by the episcopal or the secular courts. This is still the case in several states of Italy, and even in Spain and Portugal under their new constitutional governments, at least until a new code shall be enacted. It must not be forgotten that the Inquisition was established in Spain while the Cortes of Aragon and Castile were still in full vigour. The minister of justice stated in the Spanish Cortes that laws were still in force by which persons, dying in a state of heresy, cannot bequeath their property. It is not therefore sufficient for the Inquisition to be abolished in a country, in order to ensure liberty of conscience; it is not even sufficient for this purpose to establish a representative or republican government, as long as the canon law remains in force and the majority of the people do not tolerate dissent. In the small democracies of the forest cantons of Switzerland, which are exclusively Roman Catholic, no dissent from the church is allowed, and persons accused of heresy are severely punished or obliged to emigrate.

In speaking of religious liberty, people are apt to confound three things very distinct, such as toleration, liberty of conscience or of opinion, and full religious liberty. Toleration properly applies to foreigners who profess a different faith from that established in the country which they come to visit or inhabit for a time, and who are tolerated, that is to say, allowed to remain unmolested, and in some cases are permitted to have chapels of their own communion. This is now the case in almost every European country, at least with regard to particular Christian communions and to the Jews. The Lutherans and Calvinists have chapels in almost every Roman Catholic state. But this toleration is not a legal right; it is only granted during pleasure to certain nations and sects, and it applies only to foreigners and by no means to natives. Even during the rule of the Inquisition in Spain, English, Dutch, and other Protestant merchants were allowed to reside in the seaport towns, but only so long as they gave no scandal or offence to the Roman Catholic faith, and their position was therefore extremely delicate and insecure.

Liberty of conscience applies to natives as well as foreigners, and in the country where it is recognised, no one can be molested for his religious opinions or private religious practice. But the law regulates whether and under what conditions chapels or places of religious worship may be opened which dissent from the established church of the country. Much is left to the discretionary power of the executive. Thus in France, wherever there are in a town a certain number of Lutherans or Calvinists, they are allowed to have a place of religious worship, subject to certain regulations of the local authorities. Liberty of conscience is only found in countries where a considerable part of the population dissent from the established church; it does not exist in countries exclusively Roman Catholic. All the Protestant states of Europe allow liberty of conscience.

Full religious liberty is said to exist when not only every man may hold what opinions he pleases, but when every Christian sect may openly profess its faith and perform publicly its rites; and this not by especial permission, but as a matter of legal right. This is the case at present only in England and its colonies, and in the United States of North America. But even those countries cannot be said to have unlimited religious liberty, for this would mean that any one might set up any form of worship that he pleased. Now it cannot be believed that Fetish or other pagan rites would be publicly allowed in England or America. Therefore the religious liberty of England and America can only be said to extend to the various Christian and Jewish communions. And indeed it is questionable whether religious liberty in its full unlimited extent could exist in any orderly community of which the majority believe in any religion whatever; for what would be called liberty by some, would appear offence and scandal to the rest, or contravene the common law of the land: as in the case of the Mormons, were they openly to inculcate the doctrine of polygamy. Besides which the danger of proselytism must necessarily complicate the question still more. Mohammedans tolerate Christians and Jews, but will not allow any one to apostatise from the Koran.

In the case however of countries in which penal statutes exist against heretics, it is still an important question how and when and by whom those statutes are to be enforced. We have seen how the Inquisition did enforce them, and the general opinion of Europe, not merely of Protestant but of Roman Catholic Europe, has reprobated and rejected its practice. The secular power has now taken into its own hands criminal jurisdiction in all its branches in every European state, with the single exception of the Papal State, where, the government being in the hands of ecclesiastics, the jurisdiction of the canon law is kept distinct from that of the civil law, and has its own courts, of which that of the Inquisition is the principal.

It is an error to suppose that intolerance is peculiar to the Roman Catholic church; all churches and religions, Jews, Mohammedans, and heathens, Arians and orthodox, Greeks, Latins, and Protestants—all have persecuted in turn; but no other church or sect ever invented or enforced for centuries a permanent system of persecution that can be in any respect compared with that of the Inquisition.

INSANITY, in Law. [Lunacy.]

INSANITY, mental alienation, lunacy, "folie" of Esquirol, &c. Of the various ills to which man is subject none are more dreaded, and few so little understood, as that which involves the loss of his intellect. Nor can we wonder at our ignorance of the nature of this malady when we remember what mystery hangs over the workings of the mind in its healthy state. But even while our knowledge of the nature of the mind and its operations, and therefore of the exact condition on which insanity depends, remains so limited, much, it is to be hoped, may be done towards alleviating the miseries which mental disease induces by investigating the causes which influence its prevalence, by inquiring into the best mode of restoring the mind to its healthy condition, and lastly, by learning to distinguish between those slight forms of mental disorder which amount to scarcely more than eccentricity or hypochondriacal fancies, and the more important states of disturbance of the intellect which render the subjects of them dangerous to themselves or others, and justify their seclusion from society and confinement in a lunatic asylum.

After a few words relative to the history of insanity, we shall consider its varieties and the characters which each presents, its causes, nature, and the definitions proposed to characterise it, the means of recognising it, and lastly, the mode of treatment.

It is probable that many of the unfortunate persons who are described in the Old and New Testament as possessed by evil spirits were the subjects of insanity. The same may also be said of the soothsayers and ecstatic priestesses of Egypt and Greece. In later times the dependence of insanity on a diseased state of the mind, or rather of its seat and instrument, the brain, has been generally recognised, but the sense of horror originally excited by the idea of the possession by a demon still influences in some degree the feelings with which the insane are regarded. But it is gratifying to find, that, with the extension of real knowledge, views at the same time more philosophic and more humane are beginning to be adopted in relation to lunacy.

The variety of the forms of insanity is almost endless, but they may conveniently for the purpose of description be collected under the following heads:—1. Disorders of the feelings and propensities. 2. Delusions or hallucinations. 3. General derangement of the reasoning faculties. 4. Mixed forms, in which two or more of the preceding are combined; and 5, the state of imbecility or fatuity in which other kinds of mental disorder frequently terminate.

1. The first principal form which we have indicated constitutes what is termed "moral insanity" by Dr. Prichard, who describes it as "consisting in a morbid perversion of the feelings, affections, and active powers, without any illusion or erroneous conviction impressed upon the understanding; sometimes co-existing with an apparently unimpaired state of the intellectual faculties." The character of the affection varies with the degree in which the different feelings are affected: sometimes jealousy and suspicion are the prevailing passions, causing their subjects to shun their dearest relatives and to live in constant misery, though at the same time they are able to reason correctly on any topic, and at times confess that their suspicions are groundless. Other persons are tormented by a constant fear and apprehension of some undefined danger or misfortune; and with this there is often a feeling of despair, a settled melancholy, frequently of a religious character. This state of despondency (combined with delusions, one of the most frequent kinds of insanity) is at its commencement often in a considerable degree under control, and may be removed from time to time by the substitution of more cheerful feelings; but if the circumstances to which the individual is subjected be of a nature to depress or alarm, it becomes so aggravated as to lead to a loathing of existence and to suicide. The states which we have considered are generally marked by depression, but they are not unfrequently interrupted by fits of violence and preternatural excitement of short duration. In other cases this last state chiefly characterises the disease. There is then a want of self-government; the expressions are unguarded and the conduct violent. M. Pinel records a characteristic instance of this, which he terms "emportement maniaque sans delire." It is a good example of moral insanity unattended with derangement of the intellect. "A youth, the only son of a weak and indulgent mother, was the subject of uncontrolled caprice and passion. He was excited to acts of fury by any kind of opposition or remonstrance; he put to death a dog, horse, or any other animal which offended him; and excited broils in every public meeting which he joined. But when not led by his passion he enjoyed sound judgment, was fully competent to discharge all his duties, and was humane. At length he threw a woman, who had offended him, into a well, was prosecuted, and condemned to perpetual confinement in the lunatic asylum Bicêtre." An inordinate degree of pride and vanity is often the prevailing characteristic of the feelings of a disordered mind; and it is generally attended with some delusion. A propensity to mischief, the destruction of all surrounding objects, is not uncommonly displayed by the insane; another degree of the same affection is the impulse to the destruction of life. Persons affected with this morbid excess of the destructive propensity have without doubt frequently suffered the punishment due to wilful murder; many persons have been known to complain of the impulse they felt to kill, and have even begged to be confined lest they should injure others. The propensity to theft also sometimes constitutes a marked feature of insanity. Dr. Prichard mentions having seen a lunatic who would only eat when he had stolen food, and whose keeper made it a constant practice to put into some corner within his reach various articles intended for his sustenance, in order that he might take them furtively. This propensity to steal is well known to have brought disgrace on members of rich and honourable families. It is probable that in many such cases there is an uncontrollable impulse to the act, independent of any anticipation of pleasure from the subsequent possession. An excess of the sexual feeling, from a want of control over the expressions, is occasionally a source of great misery. A female modest at other times will in a state of insanity use indecent language and by her conduct discover the grossest desires.

Though we have thus described disordered states of some of the feelings and propensities as varieties of "moral insanity," it must be remembered that generally the prevalence of any of these feelings in a morbid state is attended with some delusion or disorder of the intellectual faculties; while on the other hand it is exceedingly rare to meet with instances of delusion or of general insanity with a perfectly calm and natural state of the affections; when there is not a marked derangement or excited state of any one feeling or propensity in such cases, there is a strange perverseness of temper and disposition. The modification of madness which occurs in old people, and is designated "senile madness" by Dr. Burrows, who has accurately described it, is a species of moral insanity. The moral feelings are perverted, and some of the passions in a state of excitement. "The pious," says Dr. Burrows, "become impious; the content and happy, discontented and miserable; the prudent and economical, imprudent and ridiculously profuse; the liberal, penurious; the sober, drunken." Passions which had long been dormant resume their sway, and cast shame mingled with pity over the years of declining age.

2. The term monomania has been proposed by M. Esquirol, and adopted by most writers on mental disorders, to designate those cases of insanity in which the mind is occupied by some illusion or erroneous conviction, the individual still retaining the power of reasoning correctly on matters unconnected with the subject of his delusion. The word "melancholia" has been used in the same sense, which has given rise to the erroneous notion that insanity of this kind is necessarily of a gloomy character. It is rarely that the mind of the monomaniac is otherwise perfectly sound; there is generally combined with the delusion a morbid state of the moral feelings, and in many instances a great weakness of the reasoning faculty. The subject of the delusion is very various. It may have reference to the condition of the individual's own person; thus, some fancy that they have lost their head, others that their legs are not their own, but belong to some other person, others again that they have the devil or some animal within them, that they are dead, or that they are changed to some other form, &c. Monomaniacs subjects of the last delusion are thus described by Pope,—

> "Unnumbered throngs on every side are seen,
> Of bodies changed to various forms by spleen;
> Here living tea-pots stand, one arm held out,
> One bent; the handle this, and that the spout;
> A pipkin there, like Homer's tripod walks;
> Here sighs a jar, and there a goose-pie talks."

It is probable that in many cases of delusion regarding the condition of the body there is some morbid state of the nerves, causing a sensation which excites in a mind prone to insanity an idea which the reason is unable to correct. Another kind of delusion is that which characterises the "demonomania" of some writers. It consists in a belief in the presence of invisible beings whom the lunatic sees, hears, and converses with. Religious delusions are frequently of this character: the maniac sees and communes with the Almighty or with angels. Such ideas, being very often combined with despondency, lead to suicide. Others who are subjects of such delusions fancy themselves constantly followed by some person who has the purpose of injuring them. A third kind of delusion refers to unreal events which the individuals believe to have occurred, or consists in a belief in some absurdity which has no foundation except in the patient's imagination. Such a monomaniac was the gentleman who thought he had been confined in a castle, and corresponded with a princess by writing letters in cherry-juice. The delusions which most frequently take possession of the thoughts of the proud or vain madman are referrible to the head of those which arise from abstract ideas conceived in the mind being mistaken for realities. An ambitious dreamer may for a moment imagine himself a king, but it is only a lunatic who fails soon to perceive that he is such only in his own thoughts.

There is generally some connection to be traced between the nature of the illusion and the former occupation of the monomaniac, or the ideas which have chiefly engaged his mind. Thus a butcher is said to have fancied that he had a leg of mutton hanging from his nose; a youth, the son of an attorney, fancied himself suspected of a horrible crime, and that the officers of justice were following him; persons who have had their thoughts much directed to religious subjects imagine when they become insane that they have received a charge from the Almighty; that they are persecuted by the devil, &c., &c.

3. General derangement of the intellect presents many varieties and degrees; but the distinguishing character is that the faculties of the mind generally are disordered; the patient will not speak on any subject long without betraying the defect of his reasoning power. This will in one person merely lead to strange irrational conduct and conversation—its necessary consequences; in another it will be attended with loud and violent raving (mania); in a third there will be singing, and a gay cheerful air; while a fourth case will be characterised by a low muttering incoherence. This general insanity is most frequently attended with disturbance of the bodily health. The symptoms of mental excitement frequently increase in violence for a short time, then gradually subside into a more quiet state, which too often terminates in mental imbecility.

4. The mixed forms of madness are by far the most frequent. Moral insanity, the disturbance of the moral feelings and propensities, is generally attended with some degree of weakness of the reasoning powers, or with some delusion. The general derangement of intellect has combined with it an excited state of some of the feelings; and monomania in the pure form, a mental delusion without further disorder of intellect, is very rare.

5. The duration of insanity has no certain limits; the attack may last but a few weeks, or it may continue many years. It is not uncommon to meet in lunatic asylums with persons who have been insane twenty or thirty years. When the disordered state of the mind is thus protracted, it usually terminates in loss of the intellectual faculties. The state of imbecility, dementia, or fatuity, which then succeeds, has many degrees. It commences by the loss of memory, particularly for more recent events; the mind receives impressions and perceives them, but the faculty of retaining them seems to be lost. It is this state which so frequently attends the advance of years, and gives warning of approaching decay, when the mind is otherwise sane. In the latter instance the faculties are exercised in a sound manner when the attention is roused; but frequently the words which were spoken but a few minutes previously are forgotten, though the memory for the events of youth is quite distinct. In a second degree of imbecility the power of directing the thoughts is lost; ideas come and go without order and independently of the will; questions are still heard and attempts are made to reply to them, but before the answer is half completed the train of thought is lost, and the mind and tongue wander to other subjects. In proportion as the mind becomes more and more weakened the external senses also become deadened; there is a carelessness of all that is going on around; life is reduced to the state of that of brute animals; the instincts alone guide the actions. The features are void of expression, the countenance vacant, the eyes wandering. At last even the instincts are lost; the miserable creatures seem almost unconscious of life; careless of the calls and wants of nature, they sit or lie motionless in one position, and frequently lose even the use of their limbs.

Disease in the brain may thus go on to the abolition of all the functions by which mind is manifested, without interfering with those other functions of the body on which mere existence depends. Insanity cannot be regarded as a very fatal disease. Of the lunatics at the asylum Bicêtre in the year 1822, one patient had been there 56 years; 3 had been confined upwards of 40 years; 21 more than 30 years; 50 upwards of 20 years; and 107 more than 10 years. Of those in Salpetrière seven cases had been admitted from 50 to 57 years. It is difficult to ascertain the proportional number of recoveries from insanity, so different are the statements made by different writers. While some authors have reported the cure of nearly 5 in 6 cases, others have estimated the proportion cured as less than 5 in 10; some have stated it to be as low as 5 in 15. The chance of recovery, however, varies very much according as the insanity is complicated or not with other disease; it is also influenced by the form of the disease, the period of its course, the age, sex, and constitution of the patient. Of the diseases which occasionally complicate insanity, epilepsy and paralysis are the most important. Whether paralysis affect the motion of the limbs or the speech only, the case is generally considered hopeless. The complication with true epilepsy, not mere convulsion from temporary cerebral excitement, is nearly equally unfavourable. It appears that the general derangement of the intellect is more curable than monomania, more especially in men. The state of imbecility is almost certainly incurable. The period of the disease at which it is brought under treatment has a very important influence on the chance of recovery. Of those who enter asylums soon after the commencement of the malady, 7 out of 8, or even 9 out of 10, recover; while after the third year the probable proportion of cured is not more than 1 in 30. The mean duration of cases terminating favourably seems to be from 5 to 10 months. The age most favourable for recovery from insanity is the period from the 20th to the 30th year; few recover after the 50th. Insanity is generally more curable in women than men. There is more hope of recovery when some secretion of the body is suspended which may be restored by medicine, or when a critical period, such as that of the appearance or cessation of the catamenia in women, is at hand; at such periods as those last referred to insanity has ceased after having persisted for many years.

During the period of convalescence there is great liability to relapse, but this diminishes with the increasing length of time during which the patient manifests no symptoms of unsoundness of mind. The more complete the recovery, the more likely it is to be permanent; if the judgment be strong, and the feelings neither depressed nor irritable, relapse is much less to be feared.

Causes.—Some individuals appear to be so prone to insanity that very slight causes are sufficient to induce it in them; or it is probable indeed that there is always some peculiarity in the constitution predisposing to it, since the apparent causes do not differ from those which, acting on other persons, produce other diseases and not insanity. Be this as it may, a tendency to mental and other cerebral afflictions is often observed to prevail in families, and to be transmitted from parents to offspring. An attack of insanity not only produces such a change in the system as to render it more prone to the disease than before, but the condition of the body, or rather of the brain, thus induced, may be transmitted to the children. This fact is so well known that it is unnecessary to insist further upon it. The hereditary predisposition is said to be stronger when both parents have been insane. A remarkable circumstance relating to the hereditary transmission of insanity is that the form of the disease which affects different individuals of a family is often the same, and that it attacks them about the same age. It is an opinion generally adopted that intermarriage in families gives rise to the predisposition to mental disorder, as it certainly does to weakness of body and mind. Intermarriage must tend to strengthen or maintain original peculiarities of constitution, and therefore any predisposition to disease which may exist. It is almost impossible to ascertain the proportion of cases connected with hereditary predisposition, so much is it the desire and interest of families to conceal such a circumstance.

The proportion in which the sexes are affected with insanity varies very much in different parts of the world. In Great Britain and Ireland the proportions of males to females insane is stated to be as

13 to 12. In Italy also the number of male lunatics is greater than that of the females. But in France there are more females than males insane, in the proportion of 14 to 11. Calculating from statistical accounts derived from different parts of the globe, M. Esquirol found that the proportion of men to women insane is nearly as 37 to 38. The concurrent testimony of French and English physicians tends to show that the number of the male sex affected with lunacy, as compared with the female sex, is greater in the higher than in the lower ranks of society.

Insanity is rare, though it sometimes occurs, before the period of puberty. It is from the age of 14 to 17, when a great change is taking place in the system, and when the passions begin to be more active and more liable to excitement, that insanity becomes frequent. The liability to the disease increases up to the age of 40; and although the absolute number of persons in lunatic asylums of different ages from 40 upwards becomes less and less, yet if we take into consideration that the number of persons living at the more advanced ages is also much less, we shall be led to infer, not that the liability to insanity diminishes in old age, but, on the contrary, that it rapidly increases. An excellent paper by M. Esquirol on the statistics of insanity, in which the number of insane persons at the different ages is compared with the population of the same ages, shows this in a very striking manner.

Of the causes which excite the development of insanity in individuals predisposed to it, those which act on the mind are the most efficient. It will most frequently be found that immediately before the attack the patient has suffered some severe vexation or disappointment from family troubles, pecuniary embarrassment, &c. We have seen that insanity rarely shows itself before the age in which the mind is susceptible of strong feelings, and in which the passions are excited by strong interests. A calculation made by M. Pinel represented the proportion of cases produced by moral causes, as compared with those due to physical causes, to be, in a space of five years, as 464 to 219. In one of the largest of our English asylums the proportion of cases ascertained to have been excited by moral causes was, during the years 1831 to 1836 inclusive, 431; those ascribed to physical causes, 291. The proportional influence of moral causes is, however, probably much greater than is here indicated; for in 454 cases admitted into the asylum to which we refer during the six years, no cause was assigned, and of these it must be presumed that a large number were due to moral influence. It is the slow and constant action of the depressing passions that is most instrumental in disordering the mental faculties; the violent and sudden passions much less frequently have this effect. Of the 431 cases produced by moral causes in the asylum from which we derive these facts, 289 were ascribed to trouble of mind from pecuniary distress or family disasters, grief, jealousy, disappointment, &c. Religious impressions are frequently instrumental in exciting complete derangement of the intellect in minds already sensitive and weak; 43 cases out of the 431 were traced to religious excitement. The other causes acting directly on the mind, which are more or less active in exciting insanity, are disappointed love (a not unfrequent cause in young females), fright (also acting chiefly on females), excessive study, and political excitement, which during the Revolution and succeeding years was a productive source of mental alienation in France; but cases from that cause are now comparatively rare even in that country, and of upwards of 1200 cases admitted during six years into an English asylum, two only were traced to political causes.

Of the physical causes of insanity those connected with circumstances which affect females only afford the greatest number of cases; 62 out of the 291 cases of insanity from physical causes were connected with parturition or nursing. Insanity occurring under such circumstances is termed puerperal mania, the frequency of which is not easily explained. Retardation of the appearance of the menses and their suppression are likewise occasional causes of insanity in females. The frequent dependence of mental disorder on intemperance, particularly in men, is a fact demanding much attention. Drunkenness is unfortunately a prevailing vice in England, and accordingly we find a much larger number of insane from that cause in the pauper lunatic asylums of this country than in those of France, where the abuse of intoxicating liquors is less general. Next to intemperance, the causes which act more directly on the brain itself, and give rise to inflammation or disturbance of the circulation in it, are the most influential in producing the predisposition to insanity, or in exciting it; such causes are blows on the head, fever, coup de soleil, &c. Epilepsy and, less frequently, apoplexy also lead to insanity. Lastly, any influences acting prejudicially on other parts of the body may indirectly affect the mental organ and disorder its operation.

Closely connected with the subject of the causes of insanity, and of equal importance, are the statistics of the disease. If we could ascertain all the important circumstances which accompany its greater or less prevalence in different countries, we might hope to be able to combat in some measure the evil, by adopting preventive measures. A general result, which appears to rest on correct information, is, that insanity is extremely rare in uncivilised nations, as among the natives of Africa and America. This cannot arise solely from passion less frequently disturbing their moral feeling and affections, though this is undoubtedly an influential circumstance. There seems to be an absence of the predisposition to many diseases among the uncivilised races. A less highly developed and less active condition of the brain may render it less prone to disease.

In Turkey, Spain, and Italy, insanity is comparatively less prevalent, if we may judge from the imperfect reports obtained from those countries, than in the more northern European nations and the United States of America. The proportion of lunatics to the population in England and France is, according to the calculations of Sir A. Halliday and M. Esquirol, about 1 to 1000. In Prussia the proportion, as stated by M. Jacobi, is about the same. But in Wales the proportion of insane to the population was estimated by Sir A. Halliday to be as high as 1 to 800, and in Scotland 1 to 574. In Norway too, a country somewhat similar in its physical character and in the condition of its inhabitants to Scotland, the estimate of the proportion of lunatics given by Dr. Holst is 1 to 551. A great and surprising difference is found to exist in the proportional number of insane in manufacturing and agricultural districts of England; the number being greater in the agricultural counties. This is an analogous fact to the prevalence of the disease in Wales and Scotland. There is certainly less call for the exertion of the intellectual faculties in the agricultural than in the manufacturing counties, and in Wales than in England; an explanation of the facts must therefore be sought in other circumstances. In the statistical calculations are included not merely the insane, but the idiotic from birth, and the excess in the number of unsound in mind in Wales, Scotland, and Norway, as compared with France and England, is due to the greater number of idiots, of which we can find some explanation in the hardships to which the poor of those mountainous and partly barren countries are exposed; idiotcy being a disease dependent on imperfect formation of the brain, and generally attended with other marks of an ill-developed organisation. The greater liability of the agricultural population of England to insanity is less easily accounted for. The much greater degree in which insanity presses on the lower than on the higher classes of society, is another important consideration. One cause of this is undoubtedly the much less check which is put upon the spreading of the disease by marriage with individuals whose families have the predisposition in the lower than in the higher classes. Another may be the deprivations to which parents, and particularly pregnant females, are exposed. A third is the prevalence of intemperance among the poor. The opinion has prevailed in France as well as in England, that insanity is on the increase, but the data on which this supposition is founded cannot be implicitly trusted, for the greater number and better management of lunatic asylums at the present day cause many more persons to be conveyed to them, and thus placed within the reach of statistical research; while formerly many lunatics were allowed to wander about as beggars; many from shame, or fear of the horrors of the asylum, were concealed in private families; and some, from ignorance, were punished as criminals.

The principal means of checking insanity, which the facts above detailed seem to suggest, are, 1, the prevention of the marriage of individuals predisposed by inheritance to the disease; 2, the improvement of the physical condition of the poor; 3, the encouragement of intellectual cultivation and amusements among the lower classes, as a means of checking intemperance and sensual indulgence generally; 4, a better education of the moral feelings in all classes of society, so as to discipline the passions and enable the mind to resist their disturbing influence.

Before entering on the consideration of the mode of detecting insanity, it will be necessary to inquire into the probable nature of the disease. We will first state the facts on which is founded the opinion that it is dependent on some disease in the brain. It is not requisite to offer any proof that the brain is, in the healthy state, the seat of the mental operations, the organ or instrument by which the mental principle, whatever it be, acts. Admitting this, we may naturally suppose that the cause which disturbs the functions of the mind has its seat in the same organ. Then again, although in many cases no change of structure can be found in the brain after death (which cannot surprise us if we remember the delicacy of the organ, and the slight change that would be sufficient to disorder its action), yet it is certain that morbid appearances are found much more frequently in the brain than in any other part of the body of the insane after death. The commencement of the disease is generally accompanied by pain and other symptoms of inflammation or vascular fulness of the head. In some cases we perceive a distinct connection between marked disease of the brain and insanity, as where the latter affection supervenes on epilepsy or apoplexy. The physical causes too are in many instances such as act directly on the brain; we allude to blows on the head, inflammation of the brain, coup de soleil, &c. Even the moral causes of insanity afford an argument in favour of the cerebral pathology of the disease; for the inordinate action of the brain which must attend the long continuance and great violence of a particular passion would be likely to excite diseased structure of the organ. The diseased states of other viscera, those of the abdomen for example, can only be regarded as consequences of the insanity, or as accidental complications, or if they stand at all in the relation of causes, as acting only through the medium of the brain.

It being thus premised that the brain is the seat of the disease, can we recognise any particular character in the disordered reasoning and feelings of the insane which will afford us a means of defining it, and enable us to distinguish it from other disturbed states of the mind and senses? Many writers, led by some observations of Mr. Locke, have said that "the insane reason correctly from erroneous premises." But this definition includes those only who are the subject of some delusion, while there are many lunatics who have lost the power of reasoning correctly, hence some authors have added to the above definition the sentence "or erroneously from correct premises." The definition, founded on Mr. Locke's remark, applies very well to the state of mind of many monomaniacs, who frequently act quite reasonably on the supposition of the subject of their delusion being a fact; it is in their believing what a sound man must perceive to be false that their insanity consists. Thus many persons under the influence of particular states of the brain or the senses of vision have seen spectres, but, not believing in their actual existence, were not mad. The belief in things inconsistent with the laws of nature, with the combined evidence of all our senses, or with other known facts, shows a want of reasoning power, or, according to Dr. Conolly, a want of "the comparing power;" the lunatic does not compare the evidence of one sense with that given by other senses, or with past impressions; if he did so, he would detect his error. A madman fancies his legs are made of butter, and accordingly protects them from the sun and external force; but if he used his senses of touch and sight, and compared their evidence with the sensation which excited the erroneous idea, or with the idea itself, he would perceive its falsity. There are, however, as we have said, many other cases in which, whether combined with delusions or not, there is a defect of the reasoning power, the degrees of which vary from the state of the persons who are regarded merely as somewhat silly, to that of the imbecile or fatuitous. There is, however, another less frequent form of insanity, which depends neither on reasoning from erroneous premises, nor on defect of the reasoning faculties; we allude to the state in which the moral feelings are so deranged or excited as to lead to acts which may be called insane, since the will has no longer the power of regulating them, and the individual cannot be looked upon as an accountable being. The definition adopted by Dr. Spurzheim and the phrenologists will include this last form of insanity. Insanity is by them stated to be "an aberration of any mental power (an intellectual faculty, a moral feeling, or a propensity), from the healthy state, with an inability on the part of the individual to discern its unhealthiness or to resist it."

In deciding what is and what is not insanity there will not be much difficulty if any illusion exist in the patient's mind, and its nature be known to the examiner; and when there is general derangement or defect of the reasoning powers, a careful examination will surely detect it. It is much more difficult to decide as to the existence of moral insanity when unattended with delusion or defect of the reasoning faculty, though the decision is here often of the greatest importance, as the honour or life of the individual depends upon it. No rules can be laid down for determining whether eccentric acts, or the commission of homicide, be the effect of an irresistible impulse or not; in all such cases however, the history, the dress, gestures, and manner of speaking, and the expression of the features of the individual, should be carefully attended to. In almost all insane persons there will moreover be found either symptoms of vascular excitement about the head, or an unhealthy state of the skin and of the different secretions.

There are however, as Dr. Conolly observes, two questions to be decided in every inquiry relative to the sanity of an individual. The first relates to the existence of unsoundness of mind; the second regards the treatment required, and especially the necessity of restraint, and the degree and nature of the restraint. With reference to the second question, the chief point to be considered is whether the patient be likely to injure his own person or that of others, or his own property or that of others. Medical treatment may be required in any case of insanity; but on the decision of the second question above indicated depends whether the patient shall be confined and deprived of control over his property. It is from confounding the question of the existence of madness with that of the necessity of confinement that so much injustice has been committed; to prove a man insane has been synonymous with condemning him to imprisonment. But though a man believe his legs are not his own, or that he was present at the destruction of Jerusalem, he may be a perfectly harmless and even useful member of society: shall he therefore be deprived of his liberty and of the management of his property merely on account of a single delusion? [LUNACY.]

The treatment of insanity resolves itself into the medical and the moral. The medical treatment indicated and required at the commencement of the disease consists chiefly in the attempt to reduce increased vascular excitement or slight inflammatory action. It is seldom that any violent antiphlogistic measures are required. The same treatment may be called for during the course of the disease if the symptoms of cerebral excitement or inflammation return. Sometimes want of sleep is the most marked symptom, and opiates are given with benefit. In the more chronic conditions of the disease the medical treatment is chiefly directed to the restoration and maintenance of a healthy state of all the functions of the body, particularly of the secretions. A strengthening diet is requisite in some cases; cleanliness, fresh air, and exercise in all. The best asylums afford the means of employment for the insane in the open air; but this important requisite is still neglected in some large public institutions.

The moral treatment is now recognised as an important part of the management of the insane. Formerly a lunatic was regarded with horror, as a being who had lost all relation to society, and was to be treated as a wild beast; he was confined in a gloomy filthy cell, was loaded with chains, and shut out from all influences which could cheer his mind or lead it from the subject of its delusion. The first step in the great amelioration which has taken place was effected by the efforts of M. Pinel in France, and the Quakers in England. The insane are now treated with humanity. The power of moral influences in restoring the healthy tone of the mind has been recognised as a principle, in carrying out which the chief means adopted are the following:—1. In many cases seclusion from society, chiefly with a view to remove the patient from the influence of the circumstances which produced the disorder, or which might keep up unhealthy trains of thought; but when the insanity is partial, consisting in a single delusion, this measure can scarcely be recommended, as it might, by shocking the mind, increase the malady. 2. Occupation and amusement of the mind in various ways, so as to divert the thoughts: this is an important circumstance in the treatment, though until the last few years little attended to. Everything calculated to remind the patient of his state should be avoided; the apparatus of confinement kept from his sight, and the appearance of all objects rendered as cheerful as possible. 3. The moral influence of the physician has a powerful effect on the mind of the insane; kindness will gain their confidence, while a firm though mild manner is often sufficient to restrain the most violent outbreaks of rage, and render other means of restraint unnecessary. Chains are now generally discarded from the apparatus of the lunatic asylum, and even strait waistcoats and straps are seldom required. But while measures of bodily restraint should be avoided as much as possible, it is a safe and imperative rule to remove hurtful weapons and means of mischief from the reach of the insane. All irritation of mind by threats, &c., should be avoided. 4. The convalescent should be separated from the other patients in the asylum. 5. The insane should be classified, so as to separate the quiet and timid from the noisy and violent.

In the preceding portion of this article we have not made *idiotcy* the subject of separate consideration. It is scarcely necessary to say that while *fatuity* is the state of defective intellect produced by disease late in life, *idiotcy* is the original want or deficiency of mental power. Just as the imbecility of old age has various degrees, so there are various degrees of idiotcy. One of the worst forms is that presented by the Cretins, the deformed and imperfectly organised idiots met with in the valleys of Switzerland. [CRETINS.] Idiotcy generally depends on congenital disease, but sometimes it is produced by diseases affecting the brain in very early infancy. The more remote causes are probably imperfect nourishment of the parents, or some noxious influences acting on the mother during pregnancy; the same hereditary predisposition which gives rise to insanity seems also sometimes to be productive of idiotcy. The form and size of the head in idiots may be quite natural; in many cases however it is large and deformed; in others remarkably small, particularly in the region of the forehead. The bones of the head are sometimes very thick; the brain itself disorganised, or its cavities distended with fluid. [HYDROCEPHALUS.]

INSCRIPTIONS (*Inscriptiones*), that is, records of public or private occurrences; of laws, decrees, and the like, engraved on stone, metal, and other hard substances, exhibited for public inspection. The custom of making inscriptions was far more general in the states of antiquity than in any modern country, as we see from the innumerable inscribed monuments which still exist in Persia, Egypt, Greece, Italy, and other countries subject to or colonised by the Greeks and Romans. A great number of inscriptions, especially those recording great events, laws, or decrees of the government, which it was important for every citizen to know, supplied to some extent the want of the art of printing. When, for example, the laws of the twelve tables at Rome were set up in public, this public exhibition was equivalent to their publication by means of the art of printing; for every Roman might go and read them, and, if he liked, take a copy of them for his private use. Previous to the invention of the art of printing, inscriptions set up in a public place were the most convenient means of giving publicity to that which it was necessary or useful for every citizen of the state to know. Inscriptions, therefore, are, next to the literature of the ancients, perhaps the most important sources from which we derive our knowledge of their public, religious, social, and private life, and their study is indispensable for those who desire to become intimately acquainted with the history of antiquity. For the history of the languages they are also of very great though not of equal importance. After the overthrow of the Roman empire in the west, inscriptions still continued to be made very frequently; but as the ignorance of the middle ages increased, and as all knowledge became more and more confined to the priesthood, the custom of making certain things known by means of inscriptions gradually fell into disuse, until the art of printing did away with it almost entirely.

In order to render inscriptions as permanent as possible, the ancients chose such materials as were least subject to destruction—namely, stone or metal. The stone most commonly used was marble cut in slabs, but sometimes inscriptions were engraved upon a flat surface of the unhewn rock. The most common metal was brass or bronze, though we have instances also of lead, tin, and gold being used. If we believe the accounts of the ancients, inscriptions were made even in the mythical ages (Herod., v. 59, &c.; Pausan., viii. 14, 4; ix. 11, 1); but such inscriptions existing in later times were probably forgeries, and we cannot suppose that inscriptions were made until the art of writing was pretty generally known.

We shall here pass over the arrow-headed inscriptions of Assyria [CUNEIFORM CHARACTERS], the hieroglyphics of Egypt [HIEROGLYPHICS], and the inscriptions of Etruria, Lycia, and other countries, and confine ourselves to those written in Greek and Latin.

Greek Inscriptions.—The earliest Greek inscriptions which we may safely take to have been genuine, but all of which have perished, were the lists of the victors in the Olympian games (Paus., iii. 21, 1; v. 4, 6, &c,), the records of the musical contests at Sicyon (Plutarch, 'De Mus.,' 3, 8), and the chronicle of the priestesses of Hera at Argos. The earliest among the extant inscriptions do not seem to have been made much before the year B.C. 580.

All inscriptions are composed either in prose or verse, but prose inscriptions form by far the greater number. The prose of the public documents is usually stiff, and their style is not unlike that of official documents of our own time. All Greek inscriptions are written in capital letters, and without any punctuation or separation of the several words, which often renders it difficult to read and understand them properly. Some of the earliest inscriptions are written, like the Hebrew, from the right to the left; others varied their lines, the first being written from the left to the right, and the next from the right to the left. In this manner, which is called Boustrophedon (*βουστροφηδὸν*), the laws of Solon were written, and some specimens are still extant. The method of later times was to write, like ourselves, from the left to the right. But besides these general distinctions, there occur a great variety, and some modifications of writing which are the result of mere fancy. Another important point which it is necessary to know before attempting to read Greek, and more especially Roman, inscriptions, are the abbreviations of names and words (*sigla*), which have been described and explained in several works, such as Nicolai, 'De Siglis Veterum,' Lugdun. 1703, 4to; Maffei, 'De Græcorum Siglis Lapidariis,' Verona, 1746; E. Corsini, 'Notæ Græcorum,' Florence, 1749, fol.; Placentinus, 'De Siglis Veterum Græcorum,' Rome, 1757, 4to; but the best work on the subject is Franz, 'Elementa Epigraphices Græcæ,' Berlin, 1840, 4to, which is at the same time a complete introduction to the study of Greek inscriptions.

Public or state documents were exhibited in Greece in certain places of great publicity, as the Acropolis at Athens, and sometimes whole walls were set apart for the purpose of receiving marble or metal slabs with inscriptions. Market-places and temples likewise served as repositories for inscriptions. When it was intended that an inscription should be understood by two different nations, it was written in the languages of both (*inscriptiones bilingues*), as in Greek and Assyrian (Herod., iv. 87), Greek and Phœnician (Gesenius, 'Monum. Phœnic.,' i., p. 93, &c.), Greek and Latin, Greek and Lycian (Grotefend, in the 'Transactions of the Royal Society,' iii. 2, p. 317, &c.), and Greek and Egyptian, as on the Rosetta stone in the British Museum.

The necessity of making collections of the most important inscriptions, such as contained public decrees, or interesting epigrammatic poems (of which many have found their way into the Greek Anthology), was felt by the Greeks themselves. The earliest collection we know of is that of Philochorus, under the title of Ἐπιγράμματα Ἀττικά; his example was followed by Polemon in a work *Περὶ τῶν κατὰ Πόλεις Ἐπιγραμμάτων*, and especially by Craterus in the important collection entitled Συναγωγὴ Ψηφισμάτων. Although public inscriptions were under the protection of the state, and although their violation was severely punished, we nevertheless know of several instances in which they were maliciously or frivolously destroyed or mutilated. In certain cases the state itself ordered the destruction of public documents, as when decrees were annulled or abolished. In times of war and in the destruction of towns innumerable inscriptions must have perished. Athens, as early as the time of the Persian wars, gives us an example of the destruction of public monuments, as pillars, and tombstones with inscriptions, for the purpose of building walls for the protection of the city. Still greater havoc was made by the early Christians among the ancient monuments, which were frequently used as building materials for all kinds of edifices; and if, in addition to all this, we consider the ravages of time and the destructive influence of rain and air, it is astonishing to see the immense number of inscriptions that have been preserved down to our own time.

The first modern writer who conceived the idea of making a collection of ancient inscriptions was Cyriacus of Ancona, who undertook, in 1435, a journey through Italy, Greece, and Asia Minor, and brought back a great number of inscriptions, which he collected in 3 vols. MS., which are still extant in the Barberini Library at Rome, and have often been used by subsequent collectors. After Cyriacus a long time elapsed, during which the attention of the learned was chiefly directed towards Roman inscriptions. Scipio Maffei, and after him J. Carcagni and T. M. Raponi, formed the plan of a complete collection of all inscriptions, but none of them were able to carry it into effect, and people were satisfied with books containing such inscriptions as their authors happened to meet with, or thought of particular interest. Works of this kind are:—Janus Gruter, 'Inscriptiones Antiquae totius Orbis Romani,' Heidelberg, 1602, 2 vols. fol.; 'Marmora Arundeliana' (also called 'Oxoniensia,' containing twenty-nine Greek and ten Latin inscriptions), edited by J. Selden, London, 1628, 4to, by Prideaux, Oxford, 1676, by Maittaire, London, 1732, and by Chandler, Oxford, 1763; Oct. Falconerius, 'Inscriptiones Athleticae Graecae et Latinae,' Rome, 1668, 4to, is the first attempt at a systematic collection; J. Spon, 'Itinerarium in Italiam, Illyricum, Graeciam, et Orientem,' Lugdun., 1678, 3 vols. 8vo; Thom. Reinesius, 'Syntagma Inscriptionum Antiquarum,' Lipsiae, 1682, fol.; W. Fleetwood, 'Inscriptionum Antiquarum Sylloge,' London, 1691, 8vo; R. Fabretti, 'Inscriptiones Antiquae,' Rome, 1699; A. van Dale, 'Dissertationes Antiquariæ et Marmoribus cum Romanis tum Graecis illustrandis inservientes,' Amsterdam, 1702, 8vo; A. F. Gori, 'Inscriptiones Antiquae Graecae et Romanae quae extant in Etruriae Urbibus,' Florence, 1727, 3 vols. fol.; L. A. Muratori, 'Novus Thesaurus Veterum Inscriptionum,' 1739, &c., 4 vols. fol., with a Supplement by S. Donatus, Lucca, 1765, &c., 2 vols. fol.; E. Corsini, 'Inscriptiones Atticae nunc primum e Maffei Schedis editae,' Florence, 1752, 4to. The material collected in these works was greatly enriched by the collections of inscriptions made by travellers, as Pococke, P. M. Paciaudi, Torremuzza, Passionei, Walpole, C. Vidua, and others. With the assistance of these further accessions, F. Osann began, in 1822, his 'Sylloge Inscriptionum Antiquarum Graecarum et Latinarum,' which was completed in ten fasciculi in folio, 1834; and F. G. Welcker published a smaller collection of metrical inscriptions, 'Sylloge Epigrammatum Graecorum ex Marmoribus et Libris collecta,' Bonn, 1828, 8vo.

But in the meantime the Berlin Academy had formed the plan of publishing a complete collection of all the known Greek inscriptions, of which A. Boeckh undertook the editorship. This great work bears the title, 'Corpus Inscriptionum Graecarum,' is in three huge folios (Berlin, 1828–53), and is by far the most complete collection of Greek inscriptions extant. They are arranged according to the countries and localities in which they were found; and in each particular where it is feasible, as in those of Athens, Boeckh has judiciously classified them into ten sections:—1. Acta senatus et populi, universitatum et collegiorum; 2. Tabulae Magistratuum; 3. Tituli Militares; 4. Magistratuum Catalogi; 5. Agonistica et Gymnastica; 6. Honores Imperatorum et aliorum ex domo Augusta et decreta imperatoria; 7. Tituli Honorarii; 8. Donariorum Tituli et Operum Publicorum; 9. Ordo Sacrorum, Termini, Defixiones Magicae, Supellex varia; 10. Monumenta privata, maxime sepulchralia. It is partly owing to the influence which Boeckh's 'Corpus Inscriptionum' exercised upon the scholars of our time, and partly to the political condition of Greece, that since the publication of the first volume of Boeckh's work a prodigious number of inscriptions have been brought to light by travellers, which were before unknown; all published up to 1852 have been incorporated in the 'Corpus Inscriptionum.' The principal among these subsequent works are:—Ph. Lebas, 'Inscriptions Grecques et Latines recueilles en Grèce,' Paris, 1835, &c.; Janssen, 'Musei Lugduno-Batavi Inscriptiones Graecae et Latinae,' Lugdun. Bat., 1842, 4to; L. Ross, 'Inscriptiones Graecae ineditae,' Naupliae, 1834–45, 4to; H. N. Ulrichs, 'Reisen und Forschungen in Griechenland,' Bremen, 1840, 8vo; L. Stephani, 'Reisen durch einige Gegenden des nördlichen Griechenlands,' Leipzig, 1843, 8vo; E. Curtius, 'Inscriptiones Atticae nuper repertae duodecim,' Berlin, 1843, 8vo; C. Keil, 'Sylloge Inscriptionum Boeoticarum,' Lips. 1847, 4to; the travels of Colonel Leake, Fellowes, and Hamilton: the work of Mr. Hamilton contains a large number of inscriptions from Asia Minor; and Letronne, 'Recueil des Inscriptions Grecques et Latines de l'Egypte,' 2 vols., Paris, 1842–48, 4to; and the Philological Journals of Germany, France, and England.

Latin Inscriptions.—These are not less numerous than those of Greece, and are found in great numbers at Rome, in Italy, and all the countries which were once subject to Rome. They embraced the same variety of subjects as the inscriptions in Greece, and if only the principal ones had been preserved the early constitution of Rome would be comparatively clear, whereas now there are a vast number of questions to which we can only answer by conjectures. Some of the Roman writers have, it is true, made use of the most important inscriptions for the early history of Rome, but not by any means to that extent which we could wish. The attention of Roman writers does not appear to have been so much directed towards this source of information as that of the Greeks, for there is no instance of any collection having ever been made by the Romans themselves, although some of their inscriptions were of the very highest importance in a constitutional as well as legal point of view. At the time of the overthrow of the Western Empire thousands of inscriptions must have perished, especially those engraved on metal, as the material excited the avarice of the Barbarians. But a great number was still preserved in Rome and Italy, which attracted the attention of the learned even in the early part of the middle ages.

The oldest collection of inscriptions found at Rome exists in the monastery of Einsiedeln: it is written on parchment, and probably belongs to the 10th or 11th century. It is printed in Mabillon

('Veterum Annal.,' p. 358, &c.). At the time of the revival of letters, the attention of the learned was chiefly directed towards the authors of antiquity, but ever since the 15th century attention has also been bestowed upon inscriptions. The man who first formed the idea of a comprehensive collection was the above-mentioned Cyriacus of Ancona, who undertook his travels at the request and the expense of Pope Nicholas I. The first printed collection of Latin inscriptions is that of Peutinger, who collected and published those which were found at Augsburg and in its neighbourhood on several folio leaves, under the title of 'Romanae Vetustatis Fragmenta in Augusta Vindelicorum et ejus Dioecesi,' Augsburg, 1505. Another collection, which is now extremely rare, was published by Laurentius Abstemius, at Fani in 1515, of which a second edition by F. Polyardu appeared in the same year. The collection published by the bookseller Mazocchi, at Rome, in 1520, in folio, under the title 'Epigrammata Antiqua Urbis Romae,' contains scarcely any other than sepulchral inscriptions.

After these collections of local inscriptions, B. Amantius and P. Appianus, supported by the liberal merchant Raimund von Fugger, published a general collection under the title of 'Inscriptiones Sacrosanctae Vetustatis,' Ingolstadt, 1534, fol. Soon after, the learned George Fabricius published a considerable collection of Latin inscriptions which he had made in his travels, and which had been communicated to him by his friends, in the second volume of his 'Roma,' Basle, 1550, reprinted in 1587, and at Helmstädt, 1660, fol. Martin Smetius of Bruges, during a stay of six years in Italy, made a very careful collection of inscriptions, which however were not published till after his death by Janus Douza, and with an auctarium by J. Lipsius, Lugdun.-Bat. 1588, fol. The work of Laurentius Schrader, 'Monumenta Italiae,' has one volume which contains only inscriptions which he had collected during his visits in Italy; they are arranged according to the towns in which they were found, but he does not distinguish between the earlier and later inscriptions, and he has some which are evidently not genuine. After that of Schrader followed that of Thom. Reinesius, which was mentioned above. A somewhat more complete and accurate collection of 4688 inscriptions was published by Fabretti under the title 'Inscriptionum Antiquarum, quae in Aedibus Paternis asservantur Explicatio et Additamentum,' Rome, 1699, fol. (some copies bear date of 1702, but this is only a bookseller's imposition).

But all the works here mentioned are eclipsed by the undertaking of Janus Gruterus, which was to contain all the inscriptions that had until then been made known. He took the work of Smetius as his foundation, and was actively assisted by Joseph Scaliger. The collection appeared under the title 'Inscriptiones Antiquæ totius Orbis Romani,' Heidelberg, 1603 and 1663, fol. J. G. Graevius afterwards undertook to edit a still more complete and corrected edition, but he did not live to complete his task, which fell into the hands of P. Burmann, who assisted by many other scholars, published the new edition of Gruter, under the title 'Inscriptiones Antiquae totius Orbis Romani, in absolutissimum Corpus redactae, olim auspiciis J. Scaligeri et M. Velseri, industria autem Jani Gruteri, nunc notis Marquardi Gudii emendatae, cura J. G. Graevii,' Amsterdam, 1707, fol. Marquard Gude, who had travelled in Italy, likewise prepared a collection of inscriptions for publication, which however was edited after his death by F. Hessel, Leovardiae, 1731, fol. This collection however contains many forgeries made by the notorious Ligorius. A collection of 2000 inscriptions which had been gathered by Doni, was published by Gori, 'T. B. Donii Inscriptiones Antiquae,' Florence, 1731, fol. In 1739, L. A. Muratori published his 'Novus Thesaurus Veterum Inscriptionum,' Milan, 4 vols. 4to., to which a supplement was added by S. Donatus in 2 vols., Lucca, 1765, &c. Among the collections of inscriptions published at a later time, the most important is the selection from all the known inscriptions which was published by J. C. Orelli, under the title 'Inscriptionum Latinarum selectarum amplissima Collectio ad illustrandum Romanae Antiquitatis Disciplinam accommodata, &c.; cum ineditis Hagenbuchii suisque Annotationibus,' Zürich, 1828, 2 vols. 8vo. This collection is extremely useful, especially as corrected and extended by the supplementary volume by G. Henzer, 1836; for the student should be warned that Orelli has not always published the inscriptions with that accuracy and exactness which are required in works of this kind. Another work of great value is the splendid collection of Neapolitan inscriptions made by T. Mommsen, 'Inscriptiones Regni Neapolitani Latinae,' fol. Lips. 1852. For the Latin inscriptions which are still continually being found in various parts of the world once subject to Rome, the student must consult the transactions of the various archæological societies formed in all parts of Europe, a chief object of which is the searching after, preserving, and publishing the Roman monuments existing in the particular districts in which those societies are formed. The number of Latin inscriptions now known amounts to considerably over 60,000.

Among the works to be consulted by those who wish to acquire a facility in reading and understanding Latin inscriptions, the following are of importance: Zaccaria, 'Instituzione Lapidaria,' Rome, 1770, and Venice, 1792; Morcelli, 'De Stilo Inscriptionum Latinarum Libri Tres,' Rome, 1781, and reprinted in his 'Opera Epigraphica,' Patavii, 1819, 5 vols. 8vo.; Kopp, 'Palaeographia Critica,' Mannheim, 1817–29, 4 vols. 4to.; and Orelli's Introduction to his Collection.

INSOLINIC ACID ($C_{18}H_8O_8$) results from the prolonged action of chromic acid upon cuminic acid. It is insoluble in alcohol or ether, and nearly insoluble in water, hence its name. It is bibasic, its salts being formed by the replacement of two atoms of hydrogen by metals; the neutral potash salt contains ($C_{18}H_6K_2O_8$), the acid salt ($C_{18}H_7KO_8$).

Insolinic acid is interesting as being one of the few members of the series of bibasic acids having the general formula $C_nH_{n-10}O_8$. This series is derived from the aromatic acids (benzoic, &c. $C_nH_{n-8}O_4$), and bears a similar relation to those acids that the series $C_nH_{n-2}O_8$ does the formic and acetic series of acids ($C_nH_nO_4$).

INSOLVENCY.—INSOLVENT, a man who cannot pay his debts. [BANKRUPT.] In this country, statutes have from time to time been passed for the purpose of releasing from prison, and sometimes from their debts, persons whose transactions have not been of such a nature as to subject them to the Bankrupt Laws. These statutes have been passed for a limited time only, and have been continued by subsequent enactments.

The Insolvent Law of England was consolidated by the 7 George IV. c. 57, continued and extended by the 1 & 2 Vict. c. 110, and the 2 & 3 Vict. c. 39. The law is administered by commissioners appointed by the crown, in a court called the Insolvent Debtors' Court, and in the country by the judges of the County Courts (10 & 11 Vict. c. 102).

By the 1 & 2 Vict. c. 110, no person shall be arrested upon mesne process in any civil action, except in certain cases specially provided for by the act. [ARREST.]

A person who is in prison charged in execution for any debt or damages, or otherwise committed as mentioned in the act, may, within fourteen days after the commencement of the imprisonment, petition the court for his discharge in the manner prescribed by the act, and he must in such petition state his willingness that all his real and personal estate and effects shall vest in the provisional assignee of insolvent debtors' estates; and if within twenty-one days after the like time he does not make satisfaction to the creditor at whose suit he is so charged or committed, such creditor (or other person mentioned in the act) may petition the court for an order vesting all the real and personal estate of the prisoner in such provisional assignee. When such petition has been filed, and the court has made the order above referred to, all the prisoner's real and personal estate, and everything which he may in any way acquire before his final discharge, is vested in the provisional assignee by virtue of such order when recorded, except the wearing apparel, tools, &c., of the debtor, not exceeding in the whole 20l. in value. The prisoner must also file a schedule of all debts owing by him, and of all his property. The court has power to appoint assignees for the management of the insolvent's estate; and on such assignees assenting to the appointment, all the estate of the insolvent, which was vested in the provisional assignee, becomes immediately vested in such assignees for the payment of the prisoner's debts. After the court shall have adjudged the discharge of the insolvent, he is not liable to imprisonment for any debt in respect of which the adjudication was made. But any property which he may acquire subsequent to his discharge may be taken in execution, under the provisions of the act, for the payment of his unsatisfied debts; and if the property be of such a nature that it cannot be taken in execution, the court may imprison the insolvent till he conveys such property, as the court may direct, for the general benefit of his creditors. It is unnecessary to specify the various provisions of the insolvent laws; their general object is to release the debtor from prison, to free his person from liability as to debts contracted previous to his discharge, but to make all his present and future acquired property available for the benefit of his creditors. Where new creditors have a claim on the insolvent's subsequently acquired property, which is of such a nature that it cannot be taken in execution, it may be necessary to apply to a court of equity, which in administering such estate of a deceased insolvent, will pay the creditors subsequent to the insolvency first, and then the creditors prior to the insolvency.

In cases where it is proved that the insolvent has fraudulently made away with his property, or that his debts were fraudulently contracted, the court does not discharge his person immediately, but has power to order him to be imprisoned for a period not exceeding three years from the date of his petition to the court for his discharge.

There is another statute in the English law (32 George II. c. 28), generally called the Lords' Act, from its having originated in the House of Lords, also continued and extended by subsequent enactments, which enable a debtor taken in execution for a debt not exceeding 300l. to obtain his discharge upon surrendering all his effects (except apparel, bedding, and tools of trade, not exceeding 10l. in the whole) to his creditors.

The above proceedings for relief are applicable only after arrest and imprisonment; and no relief could be obtained by a *cessio bonorum* made before imprisonment by a person not a trader within the meaning of the Bankrupt Acts, until the passing of the 5 & 6 Vict. c. 116, which has since been amended by 7 & 8 Vict. c. 70, and c. 96.

The act 5 & 6 Vict. c. 116, which came into operation 1st November, 1842, enabled a person who was not a trader within the meaning of the Bankrupt Laws, or a trader who owed debts which amounted in the whole to less than 300l., to obtain by petition a protection from the Court of Bankruptcy in London, or the Commissioners of the District Courts of Bankruptcy in the country, from all process whatever (except under a judge's order), either against his person or property, until the case was adjudicated by the court. In the interim, the insolvent's property was vested in an official assignee appointed by the court. If, on the hearing of the petition, the commissioner were satisfied with the allegations which it contained, and that the debts were not contracted by fraud, breach of trust, or by any proceedings for breach of the laws, he was empowered to make a final order for the protection of the petitioner from all process, and to cause his estate and effects to be vested in an official assignee, together with an assignee chosen by the creditors.

The act 7 & 8 Vict. c. 96, passed 9th August, 1844, is entitled "An Act to amend the law of Insolvency, Bankruptcy, and Execution." It enacts, that any prisoner in execution upon judgment in an action for debt, who is not a trader, or whose debts, if a trader, are under 300*l.*, may, without any previous notice, by petition to any court of bankruptcy, be protected from process and from being detained in prison for any debt mentioned in his schedule; and if so detained, the commissioners of any bankruptcy court may order his discharge.

The property of the insolvent may be seized for the benefit of his creditors, with the exception of the wearing apparel, bedding, and other necessaries of the petitioner (the insolvent under 7 & 8 Vict. c. 96) and his family, and the working tools and implements of the petitioner, not exceeding in the whole the value of 20*l.* Under the 7 & 8 Vict. c. 96 (§ 39), if a petitioner for protection from process (pursuant to the provisions of that act) shall wrongfully and fraudulently omit in the schedule—which schedule he is required to make (5 & 6 Vict. c. 116)—any property whatsoever, or retain or exempt out of such schedule any wearing apparel, bedding, or other necessaries, property of greater value than 20*l.*, he shall, upon conviction, be liable to be imprisoned and kept to hard labour for any period not exceeding three years.

The 7 & 8 Vict. c. 96, made a great alteration as to debts under 20*l.* The 57th section is as follows: "Whereas it is expedient to limit the present power of arrest upon final process, be it enacted, that from and after the passing of this act, no person shall be taken or charged in execution upon any judgment obtained in any of her Majesty's superior courts, or in any county court, court of requests, or other inferior court, in any action for the recovery of any debt wherein the sum recovered shall not exceed the sum of 20*l.*, exclusive of the costs recovered by such judgment."

The jurisdiction of the Court of Bankruptcy under these (protection) statutes was transferred to the Court for Relief of Insolvent Debtors in London, and to the County Courts in country cases, by the 10 & 11 Vict. c. 102.

The 7 & 8 Vict. c. 70 (often called the Gentleman's Act) provides for arrangements between persons not traders within the meaning of the Bankrupt Acts, and their creditors, under the control of the Court of Bankruptcy.

The 8 & 9 Vict. c. 127 gives to creditors the means of obtaining payment of sums under 20*l.*, besides the costs of suit, by process of summoning the debtor before the court for examination, "touching the manner and time of his contracting the debt, the means or prospect of payment he then had, the property or means of payment he still hath or may have, the disposal he may have made of any property since contracting such debt *etal.*" The court is empowered to make an order on the debtor "for the payment of his debt by instalment or otherwise;" and if the debtor fails to attend or to make satisfactory answer, or shall appear to have been guilty of fraud in contracting the debt, or to have wilfully contracted it without reasonable prospect of being able to pay it, or to have concealed or made away with his property in order to defeat his creditors, or to have had since the judgment wherewith to pay the debt, the court may commit him for any time not exceeding forty days; but such imprisonment will not operate in satisfaction for the debt. Wearing apparel and bedding of a judgment debtor, and the implements of his trade, amounting in the whole to a sum not exceeding 5*l.* in value, are exempted from seizure. The proceedings upon a judgment summons under the County Court Acts are of analogous description and effect.

The law of debtor and creditor has been a difficulty in all countries. In England an insolvent debtor may, in certain cases, be subjected to the operation of the Bankrupt Laws. If he cannot claim the benefit of the Bankrupt Laws, he is subject to the law that relates to insolvent debtors. The question of arrest and imprisonment for debt has been chiefly discussed with reference to insolvent debtors; that is, the class of debtors whose debts have not been contracted in the operations of trade or commerce, or under such circumstances as to bring them within the Bankrupt Laws.

The present very learned attorney-general (Sir R. Bethel) has introduced in the present (1860) session of parliament a bill to amend the law of bankruptcy; to assimilate the law relating to insolvents who are not traders to that relating to insolvents who are traders; and to abolish (in practice) imprisonment for debt as a means of obtaining its satisfaction. This admirable monument of Sir Richard Bethel's legislative capacity will, it is to be hoped, receive the sanction of parliament; it at once received the earnest approbation of the commercial community.

INSOLVENCY. [Bankrupt Law of Scotland.] We reserved to this place a notice of the remedy called the process of *cessio bonorum;* or surrender of goods by an insolvent debtor to his creditors on oath. This process is mentioned in the earliest records of the Scotch law under the significant name of the *bare-man process.* It was considered in the local courts, and the benefit of it was allowed, as well by way of defence as by way of suit and action, the debtor swearing that he had not in goods or gear beyond five shillings and a plack, and that of all his gains thenceforth he should assign every third penny towards payment of his debt. (Quon. Att., c. 7; stat. Will., c. 17.) But on the erection of the Court of Session, the process was drawn thither, and remained there to the exclusion of the local judicatories. It then also got the name of *cessio bonorum*, and began to be viewed through the medium of the canon and civil laws: the applicant's character was changed; he was no more a *bare man*, or in a condition of mere destitution; he was a *dyvour*, or spendthrift (from the French *devorer*, to squander or consume one's substance); and his state was infamous.

Acting on these principles the Court of Session which up till the Union usurped a legislative power in many matters, in 1606 appointed a pillory near the market-cross of Edinburgh, with a seat upon it, where all dyvours were to be exposed on a market-day at noon, with a bonnet of yellow which was to be worn by them constantly under the pain of three months' imprisonment, if apprehended at any time without the same. This, *the dyvour's habit*, was by the same authority changed in 1665, and appointed to be a coat or upper garment, whereof the one half should be yellow, and the other half brown, with a cap or hood of the same. It was also enacted in 1685, that the insolvent should specially prove how he became bankrupt; and shortly afterwards he was required to produce a certificate that *he had been the space of one month in prison.*

The consequences of such legislation might be anticipated. Continuance in jail was better than delivery on such terms; and accordingly the jails of the kingdom were in course of time filled with miserable objects. To remedy this evil an act was passed in 1696, called the *Act of Grace*, which on the preamble that "generally the burghs of the kingdom are troubled and overcharged with prisoners thrust into their prisons, who have nothing to maintain themselves, but must of necessity either starve or be a burden on the burgh," declared it lawful to the magistrates of burghs to liberate indigent debtors, if, after notice to them to that effect, the creditors failed to provide them aliment at the rate mentioned in the statute. But so entirely was the true source of the evil overlooked that in the same year an act was passed in parliament expressly forbidding the lords of session to dispense with the *bankrupt habit* in any case of *cessio bonorum*, unless the bankrupt's failing "through misfortune" were libelled, sustained, and proved; and so late as 1775, the court refused to dispense with the habit. Sounder and more humane notions began to prevail however, and generally the habit was in later times dispensed with by the court. These notions were unquestionably derived from England; and it is to the House of Lords, in its appellate jurisdiction, and to the British parliament, that the present state of the Scotch insolvent law, its restoration to its ancient condition, is to be traced.

The process of *cessio bonorum* has been modified by modern legislation, the "bankrupt habit" entirely abolished, and a jurisdiction in *cessio* conferred on the Sheriff Courts. The effect of a decree of *cessio* is not to discharge the debtor, but merely to relieve him from the operation of personal diligence or attachment of his person. It affords no protection against the attachment by his former creditors of any property which he may subsequently acquire by personal industry or otherwise, if the goods already surrendered fall short of extinguishing his debts.

INSOLVENT DEBTORS. [Insolvency.]

INSPIRATION. [Revelation.]

INSTINCT, according to Beattie ('Moral Science,' c. ii. sec. 8), is a natural impulse to certain actions which animals perform without deliberation, and without having any end in view, and without knowing why they do it. Lord Brougham, in his 'Dialogue upon Instinct' first published in his edition of Paley's 'Natural Theology,' in 1839, separates instinct into physical and mental. He says "physical instincts are independent of will or mind altogether, though they never are found except where animal life—and consequently mind, exists; but yet mind may influence them. Just so the mental instincts are independent of reason altogether, though they are found in union with it, and reason may influence them."

That the spontaneity of instinct operates unconsciously is fully established by observation. A calf butts with its head before its horns are grown; and the hen broods over the eggs of another species, or even simulated eggs, as patiently as over its own. Lastly, children in certain states of the body are observed to devour eagerly chalk and other earths which are the proper remedies for the disease, although they can have no knowledge of their beneficial nature. Generally indeed this involuntary direction of animal activity appears to be determined by certain organic states which give rise to a vague feeling of desire or aversion, whereby different species of animals are impelled to pursue or to avoid particular objects as necessary for carrying out the purposes of their existence.

In the civilised state of man it is extremely difficult to distinguish the effects of habit from the operations of nature, but from observation of the states of childhood and barbarism the ordinary instincts of the human species are apparently few in number. In children the action of sucking is generally considered instinctive, and, in a barbarous state, the first coming together of the sexes. The latter however has been denied by Hartley, as the former has by Priestley, who considers it to be purely mechanical, like the action of breathing, which Reid has incorrectly classed among instinctive actions. Besides these there are certain extraordinary instincts which are evoked by diseases, in consequence, it would seem, of a change in the mixture of the organical elements of the body. It is thus that the instinctive taste for acid drinks in the feverish patient, and the ravening of children for chalk, &c., which has been already noticed, are to be explained.

But it is in the brute creation that we meet with the most numerous examples of this original quality. The wasp, which does not itself feed upon flesh, and which knows not that a larva is to proceed from the egg which it has deposited in the sand, collects a number of green worms, and having rolled them up in a circular form, fixes them in the hole in such a manner that they cannot escape. The number of the worms so deposited is exactly proportioned to the time necessary for the growth and transformation of the wasp-worm into a fly, when it issues from the hole and is capable of procuring its own food. An instance of what we have termed extraordinary instinct is afforded by the nymphæ of the *phryganiæ*, commonly called the caddis worm, which cover themselves by means of gluten with pieces of wood, straw, small shells, or gravel. It is necessary that they should always be nearly in equilibrium with the water in which they live. To accomplish this, when their covering is too heavy they add a piece of wood; when too light, a bit of gravel.

Mr. Smellie, from whose work on the 'Philosophy of Natural History' our examples have been drawn, distinguishes two classes of instincts: those which, independent of all instruction or experience, instantaneously produce certain actions when particular objects are presented, or under the influence of peculiar feelings; and those which can accommodate themselves to peculiar circumstances and situations. Of the latter he gives as an instance the adaptive instinct of the ostrich, which, in Senegal, neglects her eggs during the day, but sits upon them in the night; whereas at the Cape of Good Hope, where the heat is less, the ostrich, like other birds, sits upon her eggs both day and night. The distinction however seems unnecessary. By the uniformity of instinctive operations nothing more is meant than that the actions of all the individuals of the species are similar when the circumstances are the same. Under different circumstances the same species may act differently, but the correspondence of individual operations will still continue.

While some writers have gone the length of reducing all the faculties of the human mind to certain instinctive principles of action, others have elevated the animal instincts to a level with rational deliberation. Locke and Lord Brougham hold that animals possess some of the faculties of reason. Descartes holds that all their actions are mechanical. Lord Brougham founds his belief on the fact that all animals have perception, and as this implies consciousness, it must lead in some degree, however restricted, to the possession of reason. This is worked out at considerable length in the dialogue mentioned above. Instinct however differs from intellect by the unerring certainty of the means it employs, the uniformity of its results, and the perfection of its works prior to and independent of all instruction or experience; and lastly, by the pursuit of nothing beyond what conduces directly either to the continuation of the individual or the propagation of the kind. But the arts of rational creatures proceed slowly through diversified and oft-repeated experiments, while the means they employ are always various, and seldom the best and most appropriate; and in their works, though falling far short of perfection in many respects, the difficulty is increased by a voluntary combination of the beautiful with the merely useful.

INSTITUT, NATIONAL. The various academies of learning in France having been dispersed during the first storms of the Revolution, a decree of the Republic, dated 3rd Brumaire of the year IV., established a national academy, called the Institut, consisting of three classes, namely, 1, physical and mathematical sciences; 2, moral and political sciences; 3, literature and the fine arts. The object was to promote the progress of learning, to publish memoirs, to make the nation acquainted with the new discoveries, and to correspond with the learned of other countries. Each class consisted of a certain number of members residing at Paris, and a number of associates in different parts of France, with a small number of foreign honorary members. ('Compte rendu et presenté au Corps Législatif le 1er jour complémentaire de l'an IV., par l'Institut National des Sciences et Arts,' 8vo., Paris, an V., (1797). Bonaparte, after he was made first consul, gave a new organisation to the National Institute, by a decree dated St. Cloud, January, 1803, and made it consist of four classes: 1, physical and mathematical sciences, divided into eleven sections, namely, geometry, mechanics, astronomy, geography, and navigation, general physics, chemistry, mineralogy, botany, rural economy and the veterinary art, anatomy and zoology, and lastly, medicine and surgery. This class consisted of 62 resident members, who could appoint 100 correspondents, including foreigners; 2nd class, French language and literature, consisting of 40 members, like the old Académie Française; 3rd class, ancient history and literature, which corresponded to the old Académie des Inscriptions et Belles Lettres. This class consisted of 40 members and 8 foreign associates, besides 60 correspondents, native and foreign; 4th class, fine arts, divided into five sections, namely, painting, sculpture, architecture, engraving, and music. This class consisted of 28 members and 8 foreign associates, and 36 correspondents, native and foreign. The class of moral and political sciences was suppressed: Bonaparte was never partial to those studies (Thibaudeau, 'Histoire du Consulat.') The vacancies in the respective classes were filled up by the members of each class, but the choice was subject to the approbation of the first consul. An annual allowance of 1500 francs was fixed for each resident member, and a salary of 6000 francs to each of the five perpetual secretaries, of whom there were two for the first class, and one for each of the other three. Annual prizes were also awarded. Bonaparte was named member for the section of mechanics. When he became emperor the Institut took the name of Imperial.

After the Restoration, Louis XVIII., by an ordonnance, 21st March, 1816, without changing the arrangement of the departments of each class, restored the old names of Académie de Sciences, Académie Française, Académie des Inscriptions et Belles Lettres, and Académie des Beaux Arts, giving to each a more independent organisation, but still keeping them united in one academical body called the Institut. Louis Philippe, by a royal ordonnance, October 26, 1832, added a fifth class, or 'Academy of Moral and Political Sciences,' divided into five sections, and consisting of 30 resident members and 5 foreign associates, besides about 30 correspondents. ('Almanach Royal et National,' for 1837.) This constitution has been continued under the Emperor Napoleon III. These various classes or academies have published many memoirs and reports; those of the Académie des Inscriptions, styled 'Mémoires de l'Institut par la classe d'Histoire et de Littérature ancienne,' 4 vols. 4to., Paris, 1818, contain many valuable papers. See also the annual 'Compte Rendu,' on the state of science in France, and the 'Discours,' or orations pronounced at the reception of every new member.

INSTITUTION. [Benefice.]

INSTRUMENTS, ASTRONOMICAL, are described under several heads.

For *Meridian* and *Vertical* circles see Circle.

For the *repeating* circle (Borda's and Reichenbach's) see Repeating Circle.

For the *sextant* and other *reflecting* instruments see Sextant. The Transit, Equatorial, Zenith Sector, and Collimator, are described under their respective titles.

For the apparatus used in measuring small quantities and subdivisions, see Micrometer; Vernier.

The machines for *measuring time* are described under Horology; Pendulum.

See also Graduation; Telescope; Observatories.

INSTRUMENTS, MUSICAL, are, 1. *Keyed*, as the organ, pianoforte, &c.; 2. *Stringed*, as the violin, violoncello, &c.; 3. *Wind*, as the flute, horn, &c.; and 4. of *Percussion*, as the drum, cymbals, &c. See the various instruments under their respective names.

INSULATION. [Electricity, Common.]

INSURANCE, FIRE. Associations for securing individuals from the ruinous consequences of accidents beyond their own control now form almost a necessary part of our social institutions. Among such combinations for the security of individuals, companies for assuring the owners of property from loss arising from fire are among those of most obvious utility, and have long been successfully established in this country. It might have been expected that the great advantage to society of individuals providing against their ruin by means of trifling annual contributions would have been felt and acknowledged on the part of the government, so far at least as to prevent the imposing of a tax upon the prudence of the people. Such however is not the fact, and a duty is levied at the rate of 3s. per cent. per annum upon the amount of property insured against destruction by fire, which rate is, in all cases, equal to 200 per cent upon the premium demanded by the insurance offices, and which is found sufficient to cover all losses, as well as to defray the expenses of management, and to afford an adequate return to capitalists who embark their property in the undertaking. This rate is 1*s*. 6*d*. per cent. for all property deemed non-hazardous; for property considered hazardous, higher rates of insurance are taken, and in some cases by special agreement only, or are wholly refused, as in the case of powder-mills. How far the imposition of this tax prevents insurances being effected it is not possible to determine. That many persons neglect to insure against the risk of fire from being compelled to pay 4*s*. 6*d*. for each 100*l*. value of their property, who would not neglect such precaution if they could attain security by payment of 1*s*. 6*d*. for a like amount, will be readily acknowledged; and the propriety of repealing this tax has been frequently urged. But this tax produced to the revenue in 1858 the sum of 1,503,010*l*., and as the amount is raised without trouble and at little cost, the tax offers to the minister of the day an inducement for its continuance which it will be difficult to overcome. There is besides no individual who can complain of special injury or grievance from the tax, and the insurance offices, by which it is collected and paid over to the government, have a special advantage in its continuance, in respect of the discount or allowance which is made to them on the amount. During a period of distress experienced by the agriculturists, the landowners and farmers of the United Kingdom, through their representatives in parliament, recently obtained an advantage over other classes of the community by the repeal of the duty upon insurance of farm produce.

The value of property insured against fire in the United Kingdom may be ascertained from the gross amount of the duty collected; this value in 1858 was 1,001,872,815*l.*; and the value of farm produce insured was 73,570,481*l.*

INSURANCE, LIFE. [REVERSIONS.]

INSURANCE, MARINE, was probably introduced into this country from Italy by the Lombards, together with many other commercial institutions, about the 13th century. The earliest specific record of its existence in legal history is a reference in Lord Coke's 'Reports,' part vi., 47 b, to a case decided in Michaelmas Term, an. 30 & 31 Eliz.; but the antiquity and prevalence of its practice is evidenced by a statute passed shortly afterwards, in the 43rd year of the reign of Elizabeth, whereby, after reciting that such assurances had existed time out of mind, a particular court called the Court of Policies of Assurance (since fallen into disuse) was constituted for the determination in a summary manner of disputes arising out of insurances.

A marine insurance is a contract entered into between persons having some pecuniary interest in ships, their cargo, or their earnings, on the one side; and other persons, who, in consideration of a premium or money payment, varying with the risk, but payable in any event, undertake to indemnify (insure) the former against specified losses at sea. The insurers are ordinarily termed *underwriters*, because they write their names at the foot of the policy opposite that portion of the whole amount to be insured which they severally insure.

Underwriting is a business still carried on principally by individuals; indeed, until 1824, it was, by statute, illegal for any partnership or corporation other than the Royal Exchange Assurance, and the London Assurance Companies, chartered to underwrite a marine policy. In that year the monopoly was abolished, and there are now three other companies that also insure against marine risks. Even prior to 1824 numerous clubs, or associations of shipowners, for mutual assurances were established, but these are now generally limited to small risks and short or coasting voyages.

The largest underwriting business in the world is transacted by the underwriters who assemble at Lloyd's,* a name which has thence acquired an unrivalled celebrity upon every sea. These underwriters constitute a powerful association, and their agents are established in every port. The losses insured against are ordinarily perils of the seas, comprising all the dangers incident to navigation; capture by a public enemy, or by pirates, or thieves; fire; jet-ons, that is, the voluntary throwing overboard of goods or merchandise in time of distress; arrests or embargoes laid on by public authority; and fraudulent conduct (called barratry) of the master or mariners. Against all these risks the underwriters severally engage to indemnify during the particular voyage, or for the period of time specified in the policy; and even if the vessel should in fact be lost at the time when the policy is executed (the circumstance being then unknown to both parties), the insurance is, by the ordinary form of these contracts, binding, it being the practice in our English policies to insure, "lost or not lost," words not usually inserted in the insurances of other nations. But the voyage marked out in the policy must be always exactly pursued; for the slightest deviation from it, except under circumstances of absolute necessity, will render the insurance ineffectual; and that, whether the loss be occasioned by the deviation or not, and whether the ship resume her proper course or not, before the loss happens. Every marine policy for a specific voyage is made under an implied warranty that the ship shall, at the time of the commencement of the risk, be seaworthy, that is, in a condition to perform the voyage; and if the fact turns out to be otherwise, the assured is not entitled to recover in the event of a loss, whether the loss proceed from the defects in her condition or from any other cause.

The assured is entitled to claim upon the policy, not only where he is able to give direct proof of the loss, but where he can show circumstances from which a loss may reasonably be presumed, as that a reasonable time has elapsed for receiving intelligence of the vessel since her departure, and that none has been received; for it will be inferred, under such circumstances, that she has foundered. (Payment by underwriters, under such circumstances, is accepted by the Court of Probate as very strong evidence of the death of those on board.) But where direct proof of the calamity is given, it may turn out that it is either a total, or a partial (called also an average) loss. A total loss, again, may be either actual or constructive; the first, where the thing insured is absolutely destroyed, so as to remain no longer in specie, or so damaged that it cannot ever arrive in specie at the port of destination; the second, where the injury it has sustained, though short of that above supposed, is so great as to make it reasonable that the assured should claim as for a total loss, leaving the underwriter to recover what he can out of the shipwreck or other calamity. And this case seems to arise whenever the nature of the loss is such as to afford reasonable ground to the assured for relinquishing the voyage altogether, as where the ship or goods, as the case may be, are so damaged as not to be worth the expense of repairs or of being forwarded. But in order to claim as for a total loss by construction only, the assured is bound formally to cede or abandon all his remaining right in the property to the underwriter; and unless notice be given him of such abandonment, within a reasonable time after intelligence of the circumstance is received, the loss may be treated as a partial one only. In every case of partial loss, the underwriter is liable to pay such proportion of the sum he has subscribed as the damages sustained by the subject of insurance bears to its whole value at the time of insurance; in the case of a total loss, he is liable to the entire amount of his total subscription, not exceeding the value of the interest in the thing lost of the person claiming under the policy. The underwriter is also, by the effect of a special clause usually introduced into policies, made liable to indemnify the assured in respect of any payment he may have properly made for salvage (that is, for the defence, safeguard, or recovery of the ship or goods), or in respect of general average, which latter subject is of a kind to require special notice. [AVERAGE.]

A stamp duty is levied upon all policies of marine insurance, which is very unfairly made to increase with the risk. (Stephen's 'Comms.,' 4th edit., vol. ii., p. 126 *et seq.* See further Arnould, 'On Marine Insurance.')

INTA'GLIO, an Italian word composed of *in* and *tagliare*, to cut. It is a term of art applied to small works of the gem class, in which the design is indented, or engraved, to distinguish them from those in which the subject or device is raised, called CAMEOS, and under which head will be found a brief notice of the history of both kinds of gem engraving. The French call such sunken works "en creux." Dies from which coins and medals are struck are also engraved in intaglio, but the process is technically known as DIE-SINKING, and has been treated of under that head. The present article will be confined to the depressed or incised engraving of precious stones.

The earliest reference to works in *intaglio* is in the sacred writings, where they are spoken of as being employed for stamps or seals for giving authority to decrees, contracts, and similar purposes. In the Old Testament frequent notices of them occur, as among others, when Tamar desired a pledge from Judah he gave her his signet (Genesis, xxxviii. 18). Another instance is in the description of the sacerdotal breastplate, where we are told the stones that were set in it were to be "like the engravings of a signet, every one with his name." (Exodus, xxxix.); showing by this general reference that such engraving, or working in intaglio, must have been well known at that time.

Among the ancient Greeks and Romans, the art of engraving in intaglio was extensively practised, from the custom of wearing a signet ring being general among freemen. The Greeks carried this branch of the fine arts to the same perfection which their genius and feeling for the beautiful enabled them to reach in all others to which they devoted their attention; but we do not trace its existence among them to a very remote date. It has been supposed that as Homer does not allude to seals they were not used in his time. The earlier engravings for signets probably were mere rude symbols; the exquisite designs produced by Pyrgoteles and others of the more renowned seal engravers of the best period of Greek art were the ultimate results of a prolonged course of experiment, practice, and observation, pursued concurrently with the progress of the arts of design generally. As was said under CAMEO, the art of gem engraving reached its highest point of perfection in the time of Alexander, and it continued to flourish for a long period afterwards. And the Greek engravers also found ample patronage in Rome, where the possession of choice engraved gems both intaglios and cameos, became a passion. The extravagant fondness of the Roman matrons for engraved gems was satirised by Juvenal, and gave rise to the remark of Pliny, that they "loaded their fingers with princely fortunes." This profusion gradually extended itself to the wearing apparel of both sexes; and among the opulent classes almost every article of use or dress glittered with engraved gems. The endless quantities of intaglios and cameos to be found in private collections as well as in the public museums of Europe would alone suffice to prove that there could have been no exaggeration in the statements of contemporaries. Many of these ancient intaglios are of the most exquisite design and execution; pure in taste, refined in drawing, and modelled with almost faultless delicacy and precision. Many of course are of very inferior quality, and it is only due to admit that though essentially imitative in style many of the cinque-cento intaglios are little inferior in execution to the finest of the antique specimens.

The gems employed by the ancient intaglio engravers (scalptores) for engraving on, were chiefly some of the many varieties of the agate, as cornelians, chalcedony, onyx, sardonyx, &c., with jasper and other opaque varieties of quartz; and sometimes even the amethyst, hyacinth, garnet, and other transparent precious stones. They likewise employed artificial gems or pastes, and some of the finest intaglios remaining are of this kind.

There has been much discussion as to the process by which the ancient gem engravers executed works which are now justly referred to as the best examples of the art. It has been a question with antiquaries whether the lathe was known; but though it is not described by any ancient writer, the works themselves seem to afford evidence of its employment, and Pliny refers to the invention of an instrument which he calls "tornum" ('Nat. Hist.' lib. vii.), which may fairly be supposed to mean a turning machine or tool. It is certain they were acquainted with the use of diamond-powder, though Naxian dust appears to have been chiefly used. The stone was first brought to the requisite form and surface by a polisher (politor): when the engraving was executed by the sculptor who employed various kinds of steel instruments, with emery, or Naxian dust, and oil, as a medium, or a diamond point set in steel; and in the finishing, to which the Greeks paid the utmost attention, probably using the diamond-dust instead of emery. (See Muller, 'Arch. der Kunst.,' § 313 &c., and the authorities there cited.)

---

* Formerly a coffee-house in Abchurch-lane, Lombard-street, now a subscription-room for the transaction of the business of marine assurance (connected with "Merchants', Captains', and Refreshment Rooms") in the Royal Exchange.

The modern practice of cutting stones in *intaglio* is by an apparatus similar in principle to the turning lathe, which gives the cutting tool, placed horizontally, a quick rotatory motion, and the stone on which the design is to be engraved being brought in contact with it, the surface is ground away or indented, till the effect required is produced. Instruments of various sizes are used, which can easily be removed and replaced, and it is usual, during the process of engraving, to supply the points of the tools with diamond-dust mixed with a little sweet oil. As the work proceeds proofs are occasionally taken in wax.

INTEGER, a whole number, as distinguished from a fraction. The more common name for a multiple of unity is "whole number," meaning a number of units without any broken unit or fraction of a unit. But if the student find any difficulty in separating the word "whole" for this purpose from its common meaning, he may accustom himself to the word integer. We are led to this remark by finding in a work of celebrity an attempt to connect the word "whole," as used in "whole number," with its general meaning, as when we say the whole is greater than its part, as follows: "Integers may be considered as numbers which refer to unity, as a whole to a part."

INTEGRAL CALCULUS. The integral calculus is the inverse of the DIFFERENTIAL CALCULUS; that is to say, if A being given, it be a question of the differential calculus to find B; then B being given, it is a question of the integral calculus to find A.

The question of finding a differential coefficient requires the attainment of the limit of the ratio of two simultaneously diminishing increments of y and x, y being a function of x: and therefore the fundamental question of the integral calculus is as follows: knowing the limit of ratio of the increment of y to the increment of x, required the function of x which y is. Or, having given a function of x, required that function of which the given function is the differential coefficient.

But though this view of the fundamental question is sufficient in pure mathematics, it is not calculated to connect the process of integration with those conceptions which the mind employs in application to geometry or mechanics. We are here accustomed to a rough species of integral calculus, with which the preceding seems at first to have no connection. Thus a number of small straight lines joined together appear to compose a curve with sufficient exactness [ARC]: we arrive at the calculation of a body's variable motion by supposing it uniform during small intervals, and accelerated at the end of each interval [ACCELERATION]; and we obtain the area of a curve with any degree of exactness by subdividing it into a large number of small curvilinear areas, for each of which we substitute a rectangle [AREA]. It should seem then that when, making the proper use of the terms [INFINITE], we say that every magnitude is made up of an infinite number of infinitely small parts, we might add that every one of the parts is of a more simple kind than the whole. Thus we appear to have a right to say that a *curve* is made of infinitely small *straight lines*; that *gradual* variable motion is made up of infinitely small separate *impulses*; that the area of a *curve* is made up of infinitely small *rectangles*. A correct understanding of this connection is the key to that of the integral calculus, and most completely so to that of its ready application.

The student who has read the articles above cited may now endeavour to connect the results, and others of the same kind, by the following generalisation. Let a whole be divided into parts, and let each part be capable of subdivision into two parts, one of which can be simply explained and found, and the other of which would be as difficult to find as the whole itself. Let $\mathrm{A}+a$ be the first part, of which A is of the former species, and a of the latter. Let $\mathrm{B}+b$, $\mathrm{C}+c$, &c., be the other parts, of which B, C, &c., are of the former, and b, c, &c., of the latter species. Then the whole question is

$$\mathrm{A}+\mathrm{B}+\mathrm{C}+\;\ldots\ldots\;+a+b+c+\;\ldots\ldots;$$

by which nothing is gained as yet, for a, b, c, &c., are of as much difficulty as the whole which is to be found. But suppose that when the number of parts is considerable, a is very small compared with A, even though A should be small; and the same of b compared with B, and c compared with C, &c. Then the whole in question is nearly found by adding A, B, C, &c.: for say that a were less than the thousandth part of A, b less than the thousandth part of B, and so on; then $a+b+c+\ldots\ldots$ is also less than the thousandth part of $\mathrm{A}+\mathrm{B}+\mathrm{C}\ldots\ldots$, or the latter may be taken for the whole with an error of less than one in a thousand. Further, suppose that by taking a number of parts sufficiently great, we can make a, b, c, &c., as small as we please in comparison of A, B, C, &c., then $a+b+c+\ldots$ may be as small a part as we please of $\mathrm{A}+\mathrm{B}+\mathrm{C}+$ &c. Consequently, by continuing this process without limit, the limit of the summation of $\mathrm{A}+\mathrm{B}+\mathrm{C}+\ldots$ is the whole required, without the necessity of paying attention to the remaining portions.

Now let ϕx be a function of x, of which the differential coefficient $\phi' x$ does not become infinite when x has any value between a and $a+b$. Then [TAYLOR'S THEOREM] it may be shown that, whenever x and $x+h$ lie between those values,

$$\phi\,(x+h)-\phi x=\phi' x\,.\,h+\mathrm{P}h^2,$$

where P is not such a function of x and h as would hinder Ph and h diminishing without limit together. Let a become $a+b$ by the steps $a+\theta$, $a+2\theta$, ….. $a+n\theta$, $n\theta$ being $=b$. We have then

$$\begin{aligned}
\phi\,(a+\theta)\;-\;\phi a\qquad\quad &= \phi' a\qquad\qquad\;\;\theta+\mathrm{A}\theta^2\\
\phi\,(a+2\theta)-\phi\,(a+\theta) &= \phi'\,(a+\theta)\;\;\theta+\mathrm{B}\theta^2\\
\phi\,(a+3\theta)-\phi\,(a+2\theta) &= \phi'\,(a+2\theta)\;\theta+\mathrm{C}\theta^2\\
\cdot\;\;\cdot\;\;\cdot\;\;\cdot\;\;\cdot\;\;\cdot\;\;\cdot\;\;\cdot\;\;\cdot & \;\;\cdot\;\;\cdot\;\;\cdot\;\;\cdot\;\;\cdot\;\;\cdot\;\;\cdot\;\;\cdot\\
\cdot\;\;\cdot\;\;\cdot\;\;\cdot\;\;\cdot\;\;\cdot\;\;\cdot\;\;\cdot\;\;\cdot & \;\;\cdot\;\;\cdot\;\;\cdot\;\;\cdot\;\;\cdot\;\;\cdot\;\;\cdot\;\;\cdot\\
\phi\,(a+n\theta)-\phi\,(a+\overline{n-1}\theta) &= \phi'\,(a+\overline{n-1}\theta)+\mathrm{Z}\theta^2
\end{aligned}$$

A, B, C, … Z, being functions of the same species as P. Sum these, remembering that $n\theta=b$, and we find that

$$\phi\,(a+b)-\phi a$$

is made up of the following series:—

$$\begin{aligned}
&\left\{\phi' a+\phi'\,(a+\theta)+\phi'\,(a+2\theta)+\;\ldots\ldots\;+\phi'\,(a+\overline{n-1}\theta)\right\}\theta\\
&\left\{\mathrm{A}\theta+\quad\;\mathrm{B}\theta\quad+\quad\mathrm{C}\theta\quad+\qquad\qquad+\quad\mathrm{Z}\theta\qquad\qquad\right\}\theta
\end{aligned}$$

If then we diminish θ without limit, or increase without limit the number of steps by which we pass from a to $a+b$, we have before us such a case as has been already described. Let p be the least value of $\phi' x$ corresponding to values of x between a and $a+b$: then the ratio of any term in the first series to the corresponding term in the second cannot fall short of that of $p\theta$ to $\mathrm{A}\theta^2$, or $\mathrm{B}\theta^2$, &c., or the ratio of p to $\mathrm{A}\theta$ or $\mathrm{B}\theta$, &c. But by diminishing θ without limit, all the preceding ratios are increased without limit; that is, the ratio of the first series to the second series is increased without limit. We have then the following equation:—

$\phi\,(a+b)-\phi a=$ limit of $\Sigma\,(\phi' x\,.\,\Delta x)$ beginning at $x=a$ and ending when $x=a+b$: or, if the interval from a to $a+b$ be divided into n parts, each of the value Δx (called θ in the preceding), and if x be made successively equal to a, $a+\Delta x$, …. $a+b-\Delta x$, then the sum of all the values of $\phi' x$, each multiplied by Δx, approaches without limit to $\phi\,(a+b)-\phi a$, when n is increased, or Δx diminished without limit. Now the same sort of convention by which [DIFFERENTIAL CALCULUS] the limit of $\dfrac{\Delta y}{\Delta x}$ is expressed by $\dfrac{dy}{dx}$ is here extended, and the limit of $\Sigma\,(\phi' x\,.\,\Delta x)$ is written $\int\phi' x\,.\,dx$. The beginning and final values of x are placed above and below the integral sign $\int$: thus the preceding equation is written

$$\phi\,(a+b)-\phi a=\int_a^{a+b}\phi' x\,dx.$$

It is common to represent the terminal value of x by x itself, as follows:—

$$\phi x-\phi a=\int_a^x\phi' x\,dx,$$

and when the initial value of x is left indefinite, then a simple constant is written for ϕa, and the symbols of the limits are omitted, as follows:—

$$\phi x=\int\phi x\,dx+\mathrm{C}.$$

Let us now suppose a given function fx, upon which we wish to perform the preceding summation, from $x=a$ to $x=a+b$; namely, making $n\,\Delta x=b$, we desire to find the limit of

$$\left\{fa+f\,(a+\Delta x)+\;\ldots\ldots\;+f\,(a+b-\Delta x)\right\}\Delta x$$

on the supposition that n is increased, or Δx diminished, without limit. This process can be performed immediately, if we can find the function which has fx for its differential coefficient. Let $f_1 x$ have the diff. co. fx; then, by the preceding theorem, the required limit of the summation is

$$f_1\,(a+b)-f_1 a.$$

For instance, so soon as we know that $\dfrac{1}{x}$ is the differential coefficient of log x, we know that log $(a+b)-$ log a is the limit of the following series,

$$\frac{\Delta x}{a}+\frac{\Delta x}{a+\Delta x}+\frac{\Delta x}{a+2\Delta x}+\;\ldots\ldots\;\frac{\Delta x}{a+b-\Delta x}$$

the number of terms being n, Δx being the nth part of b, and n being increased without limit.

The process in the article AREA will now easily show that, y being the ordinate of a curve to the abscissa x, the area contained between the ordinates whose abscissæ are a and $a+b$, the part of the abscissa b, and the curve, is $\int y dx$ taken from $x=a$ to $x=a+b$. Thus if the curve be a part of a rectangular hyperbola, whose equation is $xy=c$, or $y=\frac{c}{x}$, the area included between the ordinates, whose abscissæ are 1 and $1+k$, is $\int \frac{c}{x} dx$ from $x=1$ to $x=1+k$. But $c \log x$ is the function whose differential coefficient is $\frac{c}{x}$; whence it follows that the preceding area is $c \log(1+k) - c \log 1$ or $c \log(1+k)$ square units. This is the property of the hyperbola from which the logarithms of Napier were called *hyperbolic*. [LOGARITHMS.]

An integral is said to be definite, when its limits are given; and indefinite when they are not given.

INTEGRALS, DEFINITE. [INTEGRATION, DEFINITE.]

INTEGRATION. In the article INTEGRAL CALCULUS, the meaning of an integral was explained. The present article is devoted to the operation of integration, that is, of finding the primitive function which has a given function for its differential coefficient. Having given P a function of x required Q so that $d\text{Q} : dx$ may be P. In the article QUADRATURES, METHOD OF, is given the mode to which we must have recourse, in order to find particular values of Q, when the general methods for determining it fail. In this article we confine ourselves to what is most useful in operation, as a summary for the advanced student, not an explanation for the learner. Properly speaking, the problem requires some addition to make it definite. Thus $2x$ has x^2 for a primitive function, and also $x^2+\text{C}$, C being any constant quantity whatever. In the present article, we shall neglect this constant altogether, reminding the reader that he must never omit it in any application. If he should find in different books different functions given as the primitives of one and the same function, he will always find that those different primitives differ only by a constant quantity. Thus $(1-x)^{-1}$ and $x(1-x)^{-1}$ both occur as the primitive of $(1-x)^{-2}$; but they only differ by a constant, namely 1.

In the common process of integration, the actual passage from the differential coefficient to the primitive is always an act of memory. The algebraical work which occurs is always used either to reduce a form in which memory will not serve into one in which it will, or else to reduce the given differential coefficient to two terms, one of which can be integrated by memory, and the other of which is more simple than the original quantity.

The functions in which the simple remembrance of the forms of the differential calculus is of use are as follows:—

$$\int dx = x, \int a dx = ax, \int x^n dx = \frac{x^{n+1}}{n+1}, \int \frac{dx}{\sqrt{x}} = 2\sqrt{x},$$

$$\int \frac{dx}{x^n} = -\frac{1}{(n-1)x^{n-1}}, \int \frac{dx}{x} = \log x, \int a^x dx = \frac{a^x}{\log a}$$

$$\int \epsilon^{ax} dx = \frac{\epsilon^{ax}}{a}$$

$$\int \sin x\, dx = -\cos x, \int \cos x\, dx = \sin x, \int \frac{dx}{\cos^2 x} = \tan x$$

$$\int \frac{dx}{\sqrt{(1-x^2)}} = \sin^{-1} x, \int \frac{-dx}{\sqrt{(1-x^2)}} = \cos^{-1} x,$$

$$\int \frac{dx}{1+x^2} = \tan^{-1} x$$

To these should be added the following, which may be obtained in various ways from the methods of this article, or from peculiar artifices which are found in works on the subject.

$$\int \frac{dx}{\sqrt{(a^2-x^2)}} = \sin^{-1}\frac{x}{a}, \int \frac{-dx}{\sqrt{(a^2-x^2)}} = \cos^{-1}\frac{x}{a}$$

$$\int \frac{dx}{\sqrt{(x^2 \pm a^2)}} = \log\left\{x \pm \sqrt{(x^2-a^2)}\right\}$$

$$\int \frac{dx}{a^2-x^2} = \frac{1}{2a}\log\left(\frac{a+x}{a-x}\right) \int \frac{dx}{x^2-a^2} = \frac{1}{2a}\log\left(\frac{x-a}{x+a}\right)$$

$$\int \frac{dx}{x^2+a^2} = \frac{1}{a}\tan^{-1}\frac{x}{a} \int \frac{dx}{(a^2 \pm x^2)^{\frac{3}{2}}} = \frac{1}{a^2}\frac{x}{\sqrt{(a^2 \pm x^2)}}$$

$$\int \frac{dx}{\sin x} = \log \tan \frac{x}{2} \int \frac{dx}{\cos x} = \log \cot\left(\frac{\pi}{4} - \frac{x}{2}\right)$$

$$\int \tan x\, dx = -\log \cos x \int \cot x\, dx = \log \sin x.$$

Among the peculiar artifices of integration may be reckoned the following, which are perhaps nearly all that can be useful to a learner:—

1. The reduction of such a form as $\int \text{X} dx$ to another form $\int \text{V} dv$, in which v is a different variable. Thus $\int (a^2+x^2)^n x dx$ can be immediately reduced to $\frac{1}{2}\int (a^2+x^2)^n d.(a^2+x^2)$ or $\frac{1}{2}\int v^n dv$, where v means a^2+x^2. The second form is immediately seen to be integrable. Cases of this kind are so various that the student must form the habit of looking for them, and recognising them at sight. Sometimes a slight transformation is required, thus: $(1+a\epsilon^x)^{-1} dx$, when reduced to $(\epsilon^{-x}+a)^{-1}\epsilon^{-x}dx$ clearly shows the form $-v^{-1}dv$, where v is $\epsilon^{-x}+a$.

2. The reduction of algebraical to trigonometrical functions, and the converse. Thus $(a^2-x^2)^m x^n dx$, if x be made $a \sin\theta$, becomes $a^{2m+n+1}\cos^{m+1}\theta \sin^n\theta d\theta$. Also $\int (\sin\theta, \cos\theta) . d\theta$, if $x=\sin\theta$, becomes $\int \left\{x, \sqrt{(1-x^2)}\right\}.(1-x^2)^{-\frac{1}{2}}dx$.

3. When rational powers appear in a denominator, they should be transferred to the numerator by changing x into $1:z$. By such a transformation, we change

$$\frac{dx}{x^m\sqrt{(a+bx+cx^2)}} \text{ into } -\frac{z^{m-1}dz}{\sqrt{(az^2+bz+c)}}.$$

4. When an irrational root of a polynomial appears in the numerator, it should generally be transferred to the denominator: thus, $\sqrt{\text{X}}\, dx$ should be written $\text{X}dx : \sqrt{\text{X}}$. By such a transformation, we change

$$\sqrt{(a^2+x^2)}\,.\,dx \text{ into } \frac{a^2dx}{\sqrt{(a^2+x^2)}} + \frac{x^2dx}{\sqrt{(a^2+x^2)}}.$$

5. When, by the addition of more simple terms to the numerator, it can be made the differential of the prominent function of the denominator, such additions, with compensating subtractions, will frequently reduce the question of integration to a more simple one. Thus we alter

$$\frac{xdx}{\sqrt{(a+bx+cx^2)}} \text{ into } \frac{1}{2c}\frac{2cx+b-b}{\sqrt{(a+bx+cx^2)}}$$

$$\text{or } \frac{1}{2c}\frac{d(a+bx+x^2)}{\sqrt{(a+bx+cx^2)}} - \frac{b}{2c}\frac{dx}{\sqrt{(a+bx+cx^2)}}$$

the first term of which can be integrated as in (1), leaving the second term, which can be simply integrated.

6. The process known by the name of *integration by parts*, consists in reducing the form $\text{X}dx$ into any convenient form $\text{V}dv$, and using the obvious theorem

$$\int \text{V}dv = \text{V}v - \int v d\text{V},$$

thus the finding of $\int \text{V}dv$ is reduced to that of $\int v d\text{V}$, which it may often happen is the more simple of the two. Thus to find $\int x^m \log x dx$, we have

$$\int \log x d\frac{x^{m+1}}{m+1} = \frac{\log x \,.\, x^{m+1}}{m+1} - \int \frac{x^{m+1}}{m+1}\frac{dx}{x}$$

about the second term of which there is no difficulty. But it often happens that this method succeeds by a succession of reductions. Thus it gives

$$\int \epsilon^x x^6 dx = x^6\epsilon^x - 6\int \epsilon^x x^5 dx$$

in which the second term must be again treated in the same manner; and so on, until we arrive at $\int \epsilon^x dx$.

7. In the last mode of proceeding, it is best to form, in general terms, an *equation of reduction*, as it may be called, which furnishes the key to the reduction of each case to the one below it. Thus if $\int \epsilon^{ax}x^n dx$ be considered as a function of n, and called V_n, integration by parts gives

$$\text{V}_n = a^{-1}\epsilon^{ax}x^n - na^{-1}\text{V}_{n-1},$$

thus showing how to find $\int \epsilon^{ax}x^n dx$ as soon as $\int \epsilon^{ax}x^{n-1}dx$ is known.

8. The use of the equation of reduction depends upon our being able at last to reduce the question to that of finding a visibly known integral. Thus, if in the preceding n be an integer, we must at last come to $\int \epsilon^{ax}x^0 dx$, or $\int \epsilon^{ax}dx$, which is known. But if n were a fraction, no reduction of the value of n by units at a time would lead to an integrable form.

9. The integrable form at which we arrive by successive reductions is called the *ultimate form*. It frequently happens however that the reductions proceed by two or more steps at a time, in which case two or more ultimate forms result. For instance $\text{V}_n = \int (a^2-x^2)^{-\frac{1}{2}} x^n dx$ has for its equation of reduction

$$\text{V}_n = -\frac{x^{n-1}\sqrt{(a^2-x^2)}}{n} + \frac{n-1}{n}a^2\text{V}_{n-2}$$

Accordingly, when n is even, we are brought at last to V_0, and when n is odd, to V_1, or to $\sin^{-1}(x:a)$ and $-\sqrt{(a^2-x^2)}$.

10. In using equations of reduction, it will be found more convenient to work upwards from the ultimate form to the case required, than in the contrary way. Thus if we want $\text{V}_4 = \int \epsilon^x x^4 dx$, the equation of reduction being

$$\text{V}_n = x^n\epsilon^x - n\text{V}_{n-1},$$

we should proceed as follows:—

$$\text{V}_0 = \epsilon^x, \ \text{V}_1 = x\epsilon^x - \epsilon^x$$

$$\text{V}_2 = x^2\epsilon^x - 2(x\epsilon^x - \epsilon^x) = x^2\epsilon^x - 2x\epsilon^x + 2\epsilon^x$$

$$\text{V}_3 = x^3\epsilon^x - 3x^2\epsilon^x + 6x\epsilon^x - 6\epsilon^x$$

$$\text{V}_4 = x^4\epsilon^x - 4x^3\epsilon^x + 12x^2\epsilon^x - 24x\epsilon^x + 24\epsilon^x.$$

11. There are several cases in which the following extension of the theorem known by the name of John Bernoulli may be useful. Let u', u'', &c. be the successive differential coefficients of u with respect to x, and let v_1, v_2, v_3, &c. be the successive integrals of v with respect to x: then

$$\int u\,dv = uv - u'v_1 + u''v_2 - u'''v_3 + \ldots \pm u^{(n)}v_n \mp \int u^{(n+1)}v_n\,dv.$$

This is particularly useful when u is a rational and integral function, and v is successively integrable with ease, as when u is e^{ax}, $\sin ax$, or $\cos ax$. The process can then be continued until the remainder vanishes.

12. In the case of $\phi x dx : \psi x$, where ϕx and ψx are rational and integral functions, the integration is always possible so soon as all the roots of $\psi x = 0$ are found. The process in FRACTIONS, DECOMPOSITION OF, must be applied. When this is done, and the function thereby reduced to the sum of terms of the form $A(x-a)^{-n}dx$, the integration gives no trouble.

13. In the case of a pair of irrational roots, $a \pm \beta\sqrt{-1}$, each occurring once, the sum of the terms which they produce can be reduced to the form

$$\int(Ax+B)dx : \left\{(x-a)^2+\beta^2\right\}$$

the integral of which is

$$\frac{A}{2}\log\left\{(x-a)^2+\beta^2\right\} + \frac{B+Aa}{\beta}\tan^{-1}\frac{x-a}{\beta}.$$

14. When $\phi x dx$ is a function of powers of any one case of $ax+b$, it can, if irrational, be reduced to a rational function by assuming $ax+b=v^m$, where m is the least common multiple of all the denominators in the exponents. For dx becomes $mv^{m-1}dv : a$, and every power of $ax+b$ becomes an integer power of v.

15. The function $x^m(ax+b)^n dx$ can be integrated when either m or n is a positive integer: when n is integer, by simple expansion; when m is integer, but not n, by making $ax+b=v$, and substituting. But when both m and n are negative integers, let $x=1:y$ and after substitution, make $a+by=w$, and substitute for y.

16. The function $\phi x dx : (x^n \pm a^n)$ can be easily integrated by decomposition of fractions, the denominator never having equal roots. The same may be said if we substitute $x^{2n} \pm 2ba^n x^n + a^n$ in the denominator.

17. In $x^r(a+bx^s)^t dx$ we have an integrable function, whenever either of the following is a positive integer:—

$$\frac{r+1}{s},\text{ or } -\frac{r+1}{s}-t$$

The substitutions which succeed in the two cases are

$$a+bx^s = v^\delta,\text{ and } ax^{-s}+b=v^\delta$$

δ being the denominator of t.

18. The following transformation involves a large number of obvious cases, and is constantly occurring. If $\int\phi x dx=\psi x$, then $\int\phi(ax+b)dx=\psi(ax+b):a$.

Thus in no list would $\int\cos(ax+b)dx$ be set down, after $\int\cos x\,dx$ has been given.

19. The following integrals are worth giving separately as ultimate forms:—

$$\int\frac{dx}{x\sqrt{(x^2-a^2)}} = \frac{1}{a}\cos^{-1}\frac{a}{x},$$

$$\int\frac{dx}{x\sqrt{(a^2\pm x^2)}} = \frac{1}{a}\log\frac{x}{a+\sqrt{(a^2\pm x^2)}}$$

$$\int\frac{dx}{\sqrt{(2ax-x^2)}} = \cos^{-1}\frac{a-x}{a} = \text{vers}^{-1}\frac{x}{a}$$

$$\int\frac{dx}{\sqrt{(2ax+x^2)}} = \log\left\{x+a+\sqrt{(2ax+x^2)}\right\}$$

$$\int\frac{dx}{a+bx+cx^2} = 2\int\frac{d(2cx+b)}{(2cx+b)^2+4ac-b^2}$$

which comes under one or another of three previously given forms according as b^2-4ac is positive, nothing, or negative.

$$\int\frac{xdx}{a+bx+cx^2} = \frac{1}{2c}\log(a+bx+cx^2) - \frac{b}{2c}\int\frac{dx}{a+bx+cx^2}$$

$$\int\frac{dx}{\sqrt{(a+bx+cx^2)}} = \frac{1}{\sqrt{c}}\log\left\{2cx+b+\sqrt{\left\{4c(a+bx+cx^2)\right\}}\right\}$$

$$\int\frac{dx}{\sqrt{(a+bx-cx^2)}} = \frac{1}{\sqrt{c}}\sin^{-1}\frac{2cx-b}{\sqrt{(4ac+b^2)}}$$

$$\int\sqrt{a^2+x^2}\,dx = \frac{1}{2}x\sqrt{a^2+x^2} + \frac{a^2}{2}\log\left(x+\sqrt{a^2+x^2}\right)$$

$$\int\sqrt{a^2-x^2}\,dx = \frac{1}{2}x\sqrt{a^2-x^2} + \frac{a^2}{2}\sin^{-1}\frac{x}{a}.$$

Let $X=(a+bx+cx^2)$. Then

$$\int\sqrt{X}.dx = \frac{2cx+b}{4c}.\sqrt{X} + \frac{4ac-b}{8c}\int\frac{dx}{\sqrt{X}}$$

$$\int\sqrt{X}.xdx = \frac{1}{3c}X^{\frac{3}{2}} - \frac{b}{2c}\int\sqrt{X}.dx$$

$$\int\frac{xdx}{\sqrt{X}} = \frac{\sqrt{X}}{c} - \frac{b}{2c}\int\frac{dx}{\sqrt{X}}$$

$$\int\frac{dx}{x\sqrt{X}} = \frac{1}{\sqrt{a}}\log\frac{2a+bx-2\sqrt{(aX)}}{x}$$

$$= \frac{1}{\sqrt{-a}}\sin^{-1}\frac{bx+2a}{x\sqrt{(b^2-4ac)}}$$

$$\int X^{-\frac{3}{2}}dx = \frac{2(2cx+b)}{4ac-b^2}X^{-\frac{1}{2}}$$

$$\text{Let}\int\frac{dx}{a+b\cos x} = \frac{1}{\sqrt{(a^2-b^2)}}\cos^{-1}\frac{b+a\cos x}{a+b\cos x}$$

$$= \frac{1}{\sqrt{(b^2-a^2)}}\log\left\{\frac{b+a\cos x+\sqrt{(b^2-a^2)}.\sin x}{a+b\cos x}\right\}.$$

20. All that it remains to give are the equations of reduction for remarkable cases. Many other differentials can be integrated in a finite form: but it is impossible to give a list of all which are sometimes useful. The transformation of unknown to known forms is one of the most necessary studies of the young mathematician.

21. Let $V_{m,n}=\int(\log x)^m x^n dx$. Then

$$V_{m,n}=(\log x)^m\frac{x^{n+1}}{n+1} - \frac{m}{n+1}V_{m-1,n}$$

22. Let P stand for $Ax^a + Bx^b$, (m, n) for $\int x^m P^n dx$, g and h for $m+1+na$ and $m+1+nb$, and c for $a-b$. We shall then have

$$h(m,n)+ncA(m+a,n-1)=x^{m+1}P^n$$
$$g(m,n)-ncB(m+b,n-1)=x^{m+1}P^n$$
$$gA(m,n)+(h-c)B(m-c,n)=x^{m-a+1}P^{n+1}$$
$$hB(m,n)+(g+c)A(m+c,n)=x^{m-b+1}P^{n+1}$$

from the first pair of which formulæ of reduction can be found for n, be it positive or negative, and for m from the second pair. The most useful cases are those in which $a=0$, $b=1$, and in which $a=0$, $b=2$.

23. Let $V_n=\int(x^2\pm a^2)^{-n}dx$. Then

$$V_n = \pm\frac{x(x^2\pm a^2)^{-(n-1)}}{(2n-2)a^2} \pm \frac{2n-3}{(2n-2)a^2}V_{n-1}.$$

24. Let $V_n=\int(x^2\pm a^2)^n dx$. Then

$$V_n = \frac{x(x^2\pm a^2)^n}{2n+1} \pm \frac{2na^2}{2n+1}V^{n-1}.$$

25. Let $V_n=\int(a^2-x^2)^{-n}dx$ or $\int(a^2-x^2)^n dx$. The equations of reduction are those in (23) (using the + in $\pm$) and in (24), and writing a^2-x^2 for $x^2\pm a^2$.

26. Let $V_{m,n}=\int x^m(a^2\pm x^2)^{-n}dx$. Then

$$V_{m,n} = \mp\frac{x^{m-1}}{2(n-1)}\frac{1}{(a^2\pm x^2)^{n-1}} \pm \frac{m-1}{2(n-1)}V_{m-2,n-1}$$

$$V_{m,n} = \frac{x^{m+1}}{2(n-1)a^2}\frac{1}{(a^2\pm x^2)^{n-1}} - \frac{m+3-2n}{2(n-1)a^2}V_{m,n-1}$$

$$V_{m,n} = \pm\frac{x^{m-1}}{m+1-2n}\frac{1}{(a^2\pm x^2)^{n-1}} \mp \frac{m-1}{m+1-2n}a^2V_{m-2,n}.$$

27. Let $V_m=\int x^m(a^2\pm x^2)^{-\frac{1}{2}}$. Then

$$V_m = \pm\frac{x^{m-1}(a^2\pm x^2)^{\frac{1}{2}}}{m} \mp \frac{m-1}{m}a^2V_{m-2}.$$

28. Instead of giving a large number of forms which are all derivable from (22), it will be better to give an instance of the derivation in full. Let the case be $\int x^{-m}(2ax-x^2)^n dx$, and let the formula be required to reduce both m and n in numerical magnitude. Here, to transform the formulæ in (22),

For m write $-m$; retain n.
For A write $2a$; for B, -1.
For a write 1; for b, 2.
For g, $-m+1+n$; for h, $-m+1+2n$.
For c write -1.

The first formula connects $(-m, n)$ and $(-\overline{m-1}, n-1)$, the second $(-m, n)$ and $(-m-2, n-1)$; the third $(-m, n)$ and $(-\overline{m-1}, n)$; the fourth $(-m, n)$ and $(-m+1, n)$. By either of the first two we can therefore reduce both; by either of the last two we can reduce m only. Observe that whenever a formula will serve to raise either exponent it will also serve to reduce it. Thus, if a formula were

$$V_m=\phi(m,x)+\psi m.V_{m+1}$$

write $m-1$ for m and we have, by transformation,

$$\mathrm{v}_m = -\frac{\phi(m-1,\,x)}{\psi(m-1)} + \frac{1}{\psi(m-1)}\,\mathrm{v}_{m-1}$$

The two first formulæ become (P being $2ax-x^2$)

$$(2n-m+1)\,(-m,\,n) - 2an\,(-\overline{m-1},\,n-1) = x^{-m+1}\,\mathrm{P}^n$$
$$(n-m+1)\,(-m,\,n) - n\,(-\overline{m-2},\,n-1) = x^{-m+1}\,\mathrm{P}^n$$

from which, writing $\mathrm{v}_{m,\,n}$ for $(-m,\,n)$ or $\int x^{-m}\mathrm{P}^n dx$, we have

$$\mathrm{v}_{m,\,n} = \frac{1}{2n-m+1}\,\frac{(2ax-x^2)^n}{x^{m-1}} + \frac{2na}{2n-m+1}\,\mathrm{v}_{m-1,\,n-1}$$
$$\mathrm{v}_{m,\,n} = \frac{1}{n-m+1}\,\frac{(2ax-x^2)^n}{x^{m-1}} + \frac{n}{n-m+1}\,\mathrm{v}_{m-2,\,n-1}.$$

If it were required to reduce n in the preceding without altering m, throw the formula $x^{-m}(2ax-x^2)^n$, into the form $x^{n-m}(2a-x)^n$ and use the first of the four formulæ.

29. All the preceding forms involving $x^m\mathrm{P}^n$ are particularly in use when n is a fraction, positive or negative, with the denominator 2. These in fact form the most usual cases. Formulæ involving the powers of $\mathrm{A}+\mathrm{B}x+\mathrm{C}x^2$ are so little wanted, that they are better omitted in a work in which space is of importance.

30. Let s and c stand for sin θ and cos θ. The integral $\int \mathrm{s}^m\mathrm{c}^n d\theta$, m and n being positive integers, can be immediately found if $\mathrm{s}^m\mathrm{c}^n$ be reduced to the sum of terms of the form $\mathrm{A}\cos k\theta$ or $\mathrm{A}\sin k\theta$. But this process is laborious, except when a simple rule is mastered which seldom appears in works on trigonometry, and is seldom used except when there is some particular reason for exhibiting the result in the form of simple sines and cosines.

31. The following equations of reduction are those which are most commonly used:—

$$\int \mathrm{s}^m d\theta = -\frac{\mathrm{c}\mathrm{s}^{m-1}}{m} + \frac{m-1}{m}\int \mathrm{s}^{m-2} d\theta$$
$$\int \mathrm{c}^n d\theta = \frac{\mathrm{s}\mathrm{c}^{n-1}}{n} + \frac{n-1}{n}\int \mathrm{c}^{n-2} d\theta$$
$$\int \frac{d\theta}{\mathrm{s}^m} = -\frac{\mathrm{c}}{(m-1)\mathrm{s}^{m-1}} + \frac{m-2}{m-1}\int \frac{d\theta}{\mathrm{s}^{m-2}}$$
$$\int \frac{d\theta}{\mathrm{c}^n} = \frac{\mathrm{s}}{(n-1)\mathrm{c}^{n-1}} + \frac{n-2}{n-1}\int \frac{d\theta}{\mathrm{c}^{n-2}}$$
$$\int \mathrm{s}^m\mathrm{c}^n d\theta = \frac{\mathrm{s}^{m+1}\mathrm{c}^{n-1}}{m+n} + \frac{n-1}{m+n}\int \mathrm{s}^m\mathrm{c}^{n-2} d\theta$$
$$= -\frac{\mathrm{s}^{m-1}\mathrm{c}^{n+1}}{m+n} + \frac{m-1}{m+n}\int \mathrm{s}^{m-2}\mathrm{c}^n d\theta$$
$$\int \frac{\mathrm{c}^n d\theta}{\mathrm{s}^m} = -\frac{\mathrm{c}^{n-1}}{(m-1)\mathrm{s}^{m-1}} - \frac{n-1}{m-1}\int \frac{\mathrm{c}^{n-2} d\theta}{\mathrm{s}^{m-2}}$$
$$\int \frac{\mathrm{s}^m d\theta}{\mathrm{c}^n} = \frac{\mathrm{s}^{m-1}}{(n-1)\mathrm{c}^{n-1}} - \frac{m-1}{n-1}\int \frac{\mathrm{s}^{m-2} d\theta}{\mathrm{c}^{n-2}}$$
$$\int \frac{d\theta}{\mathrm{s}^m\mathrm{c}^n} = -\frac{1}{(n-1)\mathrm{s}^{m-1}\mathrm{c}^{n-1}} + \frac{m+n-2}{n-1}\int \frac{d\theta}{\mathrm{s}^m\mathrm{c}^{n-2}}$$
$$= \frac{1}{(m-1)\mathrm{s}^{m-1}\mathrm{c}^{n-1}} + \frac{m+n-2}{m-1}\int \frac{d\theta}{\mathrm{s}^{m-2}\mathrm{c}^n}$$
$$\int \frac{\mathrm{c}^n d\theta}{\mathrm{s}^m} = \frac{\mathrm{c}^{n-1}}{(n-m)\mathrm{s}^{m-1}} + \frac{n-1}{n-m}\int \frac{\mathrm{c}^{n-2} d\theta}{\mathrm{s}^m}$$
$$= -\frac{\mathrm{c}^{n+1}}{(m-1)\mathrm{s}^{m-1}} - \frac{n-m+2}{m-1}\int \frac{\mathrm{c}^n d\theta}{\mathrm{s}^{m-2}}$$
$$\int \frac{\mathrm{s}^m d\theta}{\mathrm{c}^n} = -\frac{\mathrm{s}^{m-1}}{(m-n)\mathrm{c}^{n-1}} + \frac{m-1}{m-n}\int \frac{\mathrm{s}^{m-2} d\theta}{\mathrm{c}^n}$$
$$= \frac{\mathrm{s}^{m+1}}{(n-1)\mathrm{c}^{n-1}} - \frac{m-n+2}{n-1}\int \frac{\mathrm{s}^m d\theta}{\mathrm{c}^{n-2}}$$
$$\int \tan^n\theta\, d\theta = \frac{\tan^{n-1}\theta}{n-1} - \int \tan^{n-2}\theta\, d\theta.$$

32. We have given the last steps in various forms, because in fact all the integrals of the form $\int x^m(a^2-x^2)^n dx$ depend upon them. For if $x = a\sin\theta$, the last integral becomes $a^{m+2n+1}\int \sin^m\theta\cos^{2n+1}\theta d\theta$.

We have now given most of the forms which will be useful in an ordinary work of reference. Further forms and examples will be found in many works on the integral calculus, but the largest collection is in Meier Hirsch's 'Integraltafeln,' Berlin, 1810, 4to, a work of which there is also an English edition.

We have omitted notice of a great many such forms as $\int x^n\epsilon^{ax}dx$, $\int x^n\epsilon^{ax}\cos nx dx$, &c., which are little used, except in particular cases. When $\phi x \,.\, \epsilon^{ax}dx$ can be integrated, it follows that $\phi x \,.\, \epsilon^{ax}\cos bx dx$, &c., can also be integrated, since the second can be made into the sum or difference of two functions of the first form, by putting for cos bx or sin bx their exponential values.

The question of the possibility of integration in finite terms can often be settled by the following theorem:—Integration and differentiation, with respect to different variables, are convertible operations; thus

$$\frac{d\int u dx}{dy} = \int \frac{du}{dy}\,dx.$$

If therefore $\int u dx$ can be found, so also can $\int (du : dy)dx$, if y be not a function of x. From this it will be seen that whenever $\phi x\epsilon^{ax}dx$ can be integrated so can $\phi x\epsilon^{ax}x^n dx$, which is obtained by n differentiations with respect to a; and also that whenever $\phi x \,.\, x^n dx$ can be integrated, so can $\phi x x^n (\log x)^m dx$, which is obtained by m differentiations with respect to n.

Functions involving the transcendental forms $\sin^{-1}\phi x$, &c., can sometimes be reduced to more algebraical forms by integration by parts. Thus,

$$\int \mathrm{v}\sin^{-1}\mathrm{x} \,.\, dx = \sin^{-1}\mathrm{x} \,.\int \mathrm{v}dx - \int \frac{\mathrm{x}'\int \mathrm{v}dx}{\sqrt{(1-\mathrm{x}^2)}}\,dx$$
$$\int \mathrm{v}\log \mathrm{x}dx = \log \mathrm{x} \,.\int \mathrm{v}dx - \int \frac{\mathrm{x}'\int \mathrm{v}dx}{\mathrm{x}}\,dx, \text{ \&c.}$$

in which x' means $d\mathrm{x} : dx$.

INTEGRATION DEFINITE. In the preceding article we have given some idea of the usual modes of integration. The results, which in the present article are given under the name of *definite integrals*, are mostly cases in which it is possible to find an integral when both limits are given [INTEGRAL CALCULUS]; but not possible to find the integral in all cases. If we can integrate $\phi x dx$ generally, that is, if we can find the function $\phi_1 x$, of which ϕx is the differential coefficient, we can always express the integral, the limit of the summation in the article just referred to, as follows:—

$$\int_a^b \phi x dx = \phi_1 b - \phi_1 a$$

but it frequently happens that ϕx is a function for which this cannot be done in a finite form, except for certain values of a and b. And it happens almost as frequently that these practical values are of particular importance.

But the view of definite integrals which best shows their utility is the consideration of them as fundamental modes of expression. The ordinary symbols of algebra, it is well known, are incompetent to express in finite terms by far the greater number of integrals. Consequently the integrals themselves become modes of expression, and frequently the only ones. When we find a language with which we have much to do, and which has words which cannot be translated, we adopt the words of that language into our own. Precisely the same thing is done in the case of definite integrals. Thus, in FACTORIALS, we adopt the integral $\int_0^\infty \epsilon^{-x}x^n dx$, as the fundamental mode of expression for a function till then inexpressible, which becomes $1\ 2 \,.\, 3 \ldots n$ whenever n is an integer, and remains intelligible, though not very easily found, when n is a fraction.

Further to illustrate this, let us suppose that the integral calculus had made some progress before the conception of a logarithm had been formed: a thing which might easily have happened. It would then have been found that $\int x^{-1}dx$ was wholly unattainable, a function which algebra could not express in finite terms. It would therefore itself have become a mode of expression, and it would soon have been proved that

$$\int_1^a \frac{dx}{x} + \int_1^b \frac{dx}{x} = \int_1^{ab} \frac{dx}{x}.$$

Here then would have been an obvious indication of the existence of a function proper to be made use of in performing multiplication by means of addition, &c.; and tables of the values of $\int_1^a x^{-1}dx$ would have been formed by the method of quadratures [QUADRATURES,] or otherwise; which would, so it happens, have been a much easier task than that which fell on the first calculators of logarithms. For all this however it happens that we are prepared by knowing logarithms and their properties; so that $\int x^{-1}dx$ is seen to be log. $x + \mathrm{C}$, and $\int_1^a x^{-1}dx$ to be log. a: the logarithms throughout this article being Naperian. But we are not equally ready for $\int \epsilon^{-t^2}dt$, nor for $\int \epsilon^{-x}x^n dx$ (except when n is integer) nor for $\int \cos x^n dx$: and accordingly we are obliged to study the properties of these functions as fundamental modes of expression.

To give some idea of the use of this view, we exhibi a mode of solving the following partial differential equation,

$$\frac{du}{dt} = a\,\frac{d^2u}{dx^2},$$

the general solution of which cannot be expressed in finite terms. It will easily be seen that $c\epsilon^{\mu t+\nu x}$ is a solution for any value of c and ν, provided only that $\mu = a\nu^2$: and also that the sum of any number of such terms is a solution. Hence we assume an indefinite number of such terms giving to c the form $\phi\nu . d\nu$, and summing them with such values of ν as will make the whole represent

$$\int_p^q \phi\nu \,.\, \epsilon^{\nu x+a\nu^2 t}\, d\nu :$$

and we then see that this integral is a solution or general value of u, whatever the function $\phi\nu$ may be, and whatever may be the values of p and q. By a reduction which is rendered easy by some of the results presently mentioned, this solution is thrown into the form

$$u = \int_{-\infty}^{+\infty} \psi\,(x+2v\sqrt{at})\; \epsilon^{-v^2}\, dv,$$

where ψ may be the symbol of any function. From this it is clear that the given differential equation has numberless solutions which ordinary symbols are incapable of expressing in finite terms. The treatise in the Library of Useful Knowledge on the Differential Calculus, Gregory's 'Examples of the Differential Calculus,' and the 'Cambridge Mathematical Journal,' and its successor, contain various examples of this mode of expression applied to differential equations.

We now proceed to give a selection from the enormous number of definite integrals which has been given. They have been found by detached methods, so that we could not attempt to give anything more than the results. Our article is intended for reference to the forms which it is probable will be noted in future elementary works, and which the mathematical reader may also wish to refer to. In order to avoid risk of broken or dropped letters, in an article in which the correct printing of the limits is of the utmost importance, we shall print what is usually denoted by $\int_a^b \phi x dx$ in the following way, $\int \phi x dx\ [a, b]$. Any conditions as to the values of constants will be expressed before the integral. It need hardly be said that the article FACTORIALS must be considered as a part of the present one.

Among the integrals which clearly depend on, or are connected with, factorials, are the following :—

$$(m+1<n) \int \frac{x^m dx}{1+x^n}\ [0, \infty] = \frac{\pi}{n \sin\left(\frac{m+1}{n}\pi\right)}$$

$$(m+1<n) \int \frac{x^m dx}{(1+x)^n}\ [0, \infty] = \frac{\Gamma(m+1)\ \Gamma(n-m-1)}{\Gamma n}$$

$$(m \text{ and } n \text{ positive})\ \int x^{m-1}(1-x)^{n-1} dx\ [0, 1] = \frac{\Gamma m \,.\, \Gamma n}{\Gamma(m+n)}$$

$$\int \frac{x^{m-1}(1-x)^{n-1}}{(x+a)^{m+n}}\, dx\ [0, 1] = \frac{\Gamma m \,.\, \Gamma n}{a^n (1+a)^m\ \Gamma(m+n)}$$

$$(n \text{ positive}) \int (-\log x)^{n-1} dx\ [0, 1] = \Gamma n$$

$$(m \text{ and } n \text{ positive}) \int x^{m-1}\,(-\log x)^{n-1}\, dx\ [0, 1] = m^{-n}\,\Gamma n$$

$$(a \text{ and } n \text{ positive}) \int x^{n-1}\,\epsilon^{-ax}\, dx\ [0, \infty] = a^{-n}\Gamma n$$

$$(n \text{ positive}) \int \epsilon^{-x^n}\, dx\ [0, \infty] = \frac{1}{n}\ \Gamma\ \frac{1}{n}$$

$$\int \epsilon^{-x^2} dx\ [0, \infty] = \tfrac{1}{2}\sqrt{\pi}.$$

Tables of the value of $(2 : \sqrt{\pi}) \int \epsilon^{-x^2} dx\ [0, a]$, which are of great importance in the theory of probabilities, are given in modern works on that subject. The following expression by means of a continued fraction is useful. Let $q = 1 : 2a^2$, then

$$\int \epsilon^{-x^2} dx\ [a, \infty] = \frac{\epsilon^{-a^2}}{2a}\ \frac{1}{1+}\ \frac{q}{1+}\ \frac{2q}{1+}\ \frac{3q}{1+}\ \frac{4q}{1+}\ \&c.$$

$$(n>-1) \int \frac{1-x^n}{1-x}\, dx\ [0, 1] = \gamma + \frac{d \log \Gamma(1+n)}{dn};$$

γ being as in FACTORIALS.

One of Euler's integrals, generally called the second Eulerian integral, the factorial integral being the first, he denoted by the symbol

$$\left(\frac{n}{m}\right);\ \text{it is} \int x^{n-1}(1-x^k)^{\frac{m}{k}-1} dx\ [0, 1],$$

and it is included in those already given.

There is a class of multiple integrals closely connected with factorials, which may be made to save much trouble in applications to geometry. We shall take three variables as a specimen, but the same formulæ may be written with any number. The triple integration being made for all positive values which give $x+y+z$ not exceeding l, we have (a, b, c, being positive)

$$\int x^{a-1}\,y^{b-1}\,z^{c-1}\, dxdydz = \frac{\Gamma a \,.\, \Gamma b \,.\, \Gamma c}{\Gamma(a+b+c+1)}\ l^{a+b+c}$$

$$\int x^{a-1}\,y^{b-1}\,z^{c-1} f(x+y+z)\, dxdydz$$

$$= \frac{\Gamma a \,.\, \Gamma b \,.\, \Gamma c}{\Gamma(a+b+c)} \int x^{a+b+c-1} fx dx\ [0, l]$$

Similarly, the condition being that

$$\left(\frac{x}{P}\right)^p + \left(\frac{y}{Q}\right)^q + \left(\frac{z}{R}\right)^r$$

shall not exceed l, we have

$$\int x^{a-1}y^{b-1}z^{c-1} \int \left\{\left(\frac{x}{P}\right)^p + \left(\frac{y}{Q}\right)^q + \left(\frac{z}{R}\right)^r\right\} dxdydz$$

$$= \frac{P^a Q^b R^c}{pqr}\ \frac{\Gamma\frac{a}{p} \cdot \Gamma\frac{b}{q}\ \Gamma\frac{c}{r}}{\Gamma\left(\frac{a}{p}+\frac{b}{q}+\frac{c}{r}\right)} \int x^{\frac{a}{p}+\frac{b}{q}+\frac{c}{r}-1}\ fx dx\ [0, l].$$

We shall now give some specimens of the results of functions involving trigonometrical quantities. One of the most important of this class is the following :—

$$\int x^{-1} \sin bx\, dx\ [0, \infty] = \pm \tfrac{1}{2}\pi$$

according as b is positive or negative.

$$(a \text{ pos}) \int \frac{\cos ax\ dx}{1+x^2}\ [0, \infty] = \int \frac{\sin ax \,.\, x dx}{1+x^2}\ [0, \infty] = \frac{\pi}{2}\ \epsilon^{-a}$$

$$\int \epsilon^{-ax} \cos bx dx\ [0, \infty] = a : (a^2+b^2)$$

$$\int \epsilon^{-ax} \sin bx dx\ [0, \infty] = b : (a^2+b^2) :$$

from these come

$$\int \cos bx dx\ [0, \infty] = 0,\ \int \sin bx dx\ [0, \infty] = 1;$$

and from these come two equations which have been much used, long before they were openly expressed,

$$\sin \infty = 0,\ \cos \infty = 0.$$

Some difference of opinion exists about these equations, which in fact involve a great deal of what has been done by mathematicians[*] in the last thirty years.

When a and n are both positive

$$\int \epsilon^{-ax} \cos bx \,.\, x^{n-1} dx\ [0, \infty] = \frac{\Gamma n \,.\, \cos\left\{n \tan^{-1}(b : a)\right\}}{(a^2+b^2)^{\frac{n}{2}}}$$

$$\int \epsilon^{-ax} \sin bx \,.\, x^{n-1} dx\ [0, \infty] = \frac{\Gamma n \,.\, \sin\left\{n \tan^{-1})b : a)\right\}}{(a^2+b^2)^{\frac{n}{2}}}$$

$$\int \cos x^m \,.\, x^n dx\ [0, \infty] = \frac{1}{m}\ \Gamma\left(\frac{n+1}{m}\right) \cos\left(\frac{n+1}{2m}\pi\right)$$

$$\int \sin x^m \,.\, x^n dx\ [0, \infty] = \frac{1}{m}\ \Gamma\left(\frac{n+1}{m}\right) \sin\left(\frac{n+1}{2m}\pi\right)$$

$$a<b \int \frac{\sin ax}{\sin bx}\ \frac{dx}{1+x^2}\ [0, \infty] = \frac{\pi}{2}\ \frac{\epsilon^{a}-\epsilon^{-a}}{\epsilon^{b}-\epsilon^{-b}}.$$

But when $a = 2mb \pm c$, m being an integer, the preceding integral is

$$\frac{\pi}{2}\ \frac{\epsilon^{c}+\epsilon^{-c}-2\epsilon^{-a}}{\epsilon^{b}-\epsilon^{-b}}.$$

This is a specimen of a sort of discontinuity which very frequently occurs, and from not attending to which mistakes have often arisen.

If we call $\frac{1}{2}(\epsilon^x + \epsilon^{-x})$ and $\frac{1}{2}(\epsilon^x - \epsilon^{-x})$ the *hyperbolic* cosine and sine of x, and denote them by h. cos x and h. sin x, we have, the limits being 0 and ∞, and a being less than π,

$$\int \frac{\text{h. } \sin ax}{\text{h. } \sin \pi x} \cos cx\ dx = \frac{1}{2}\ \frac{\sin a}{\cos a + \text{h. } \cos c}$$

$$\int \frac{\text{h. } \cos ax}{\text{h. } \cos \pi x} \cos cx\ dx = \frac{\cos \frac{1}{2}a \,.\, \text{h. } \cos \frac{1}{2}c}{\cos a + \text{h. } \cos c}$$

$$\int \frac{\text{h. } \cos ax}{\text{h. } \sin \pi x} \sin cx\ dx = \frac{1}{2}\ \frac{\text{h. } \sin c}{\cos a + \text{h. } \cos c}$$

$$\int \frac{\text{h. } \sin ax}{\text{h. } \cos \pi x} \sin cx\ dx = \frac{\sin \frac{1}{2}a \,.\, \text{h. } \sin \frac{1}{2}c}{\cos a + \text{h. } \cos c}$$

$$\int \frac{\sin cx\, dx}{\epsilon^{2\pi x}-1}\ [0, \infty] = \frac{1}{4}\ \frac{\epsilon^{c}+1}{\epsilon^{c}-1} - \frac{1}{2c}.$$

The integral $4n \int \frac{t^{2n-1}\, dt}{\epsilon^{2\pi t}-1}\ [0, \infty]$ is the nth number of Bernoulli [NUMBERS OF BERNOULLI], meaning that opposite to which $2n-1$ is written in the article cited.

---

[*] With regard to these equations, it must be observed that they are not to have their algebraical consequences; thus, $\sin^2 \infty$ is not 0, but $\frac{1}{2}$. The truth seems to be, as far as yet appears, that any function ϕx, which becomes indefinite in form, by the angle x becoming infinite, is properly represented by $\int \phi x dx$ [0, 2π] divided by 2π.

As specimens of the reduction of definite integrals, the integrals

$$\int\frac{\epsilon^{-a^2t^2}\cos axt\,dt}{1+t^2}\,[0,\infty]\text{ and }\int\frac{\epsilon^{-a^2t^2}\sin axt\,tdt}{1+t^2}\,[0,\infty]$$

are severally equal to

$$\frac{\sqrt{\pi}\,.\,\epsilon^{a^2}}{2}\Big\{\epsilon^{-ax}\int\epsilon^{-t^2}dt\,[-\infty,\tfrac{1}{2}x-a]$$

$$\pm\,\epsilon^{ax}\int\epsilon^{-t^2}dt\,[\tfrac{1}{2}x+a,\infty]\Big\}$$

the first having $+$, the second $-$. Also

$$\int\frac{\epsilon^{-a^2t^2}dt}{1+t^2}\,[0,\infty]=\sqrt{\pi}\,.\,\epsilon^{a^2}\int\epsilon^{-t^2}dt\,[a,\infty].$$

The following is fundamentally important,

$$\int\epsilon^{-a^2x^2}\cos bxdx\,[0,\infty]=\frac{\sqrt{\pi}}{2a}\,\epsilon^{-\frac{b^2}{4a^2}}$$

The integral $\int\frac{dx}{\log x}\,[0,a]$ has been tabulated [Diff. Calc., L. U. K., p. 662] by Soldner, and a great many integrals may be found from it. Soldner proposes to call it the *Logarithm-integral* of a, and to denote it by the abbreviation li. a. Adopting this notation, we have then, both in definite and indefinite forms,

$$\int\frac{x^m dx}{\log x}=\text{li. }x^{m+1}\qquad\int\frac{\epsilon^{\pm x}dx}{x}=\text{li. }\epsilon^{\pm x}$$

$$\int\frac{dx}{\log(a+bx)}=\frac{1}{b}\text{li. }(a+bx)\quad\int\epsilon^{\epsilon^x}dx=\text{li. }\epsilon^{\epsilon^x}$$

and so on.

Of miscellaneous integrals there is an immense number, of which we give a few instances:—

$$\int\frac{(1-v^m)(1-v^n)\,dv}{(1-v)\log v}\,[0,1]=\log\frac{\Gamma(1+m\,\Gamma(1+n)}{\Gamma(1+m+n)}$$

$$(a\text{ pos.})\int\frac{x\tan x\,dx}{a^2+x^2}\,[0,\infty]=\frac{\pi}{\epsilon^{2a}+1}$$

$$(a\text{ pos.})\int\frac{x\cot xdx}{a^2+x^2}\,[0,\infty]=\frac{\pi}{\epsilon^{2a}-1}$$

$$(a\text{ pos.})\int\epsilon^{-ax}\sin bx\,.\,x^{-1}dx\,[0,\infty]=\tan^{-1}\,(b:a)$$

$$\int\frac{\epsilon^{-ax}\cos bx-\epsilon^{-\alpha x}\cos\beta x}{x}dx\,[0,\infty]=\frac{1}{2}\log\frac{\alpha^2+\beta^2}{a^2+b^2}$$

if neither α nor a be negative.

$$\int\epsilon^{-x^2-\frac{a^2}{x^2}}dx\,[0,\infty]=\frac{1}{2}\sqrt{\pi}\,\epsilon^{-2a}$$

$$\int\frac{x\sin x\,dx}{1-2a\cos x+a^2}\,[0,\pi]=\frac{\pi}{a}\log(1+a)\text{ or }\frac{\pi}{a}\log\left(1+\frac{1}{a}\right)$$

according as a is less or greater than unity.

Among the means of producing or using definite integrals which are comprehensive enough to deserve the name of methods, there are four which particularly deserve the attention of elementary writers.

The first is Laplace's mode of finding the approximate value of a definite integral in which large constant exponents occur. Let ϕx be a function of x, such as $\epsilon^{-x}x^n$ or $x^n.(1-x)^m$, &c., in which n, m, &c., are considerable exponents. Let this function vanish when $x=a$ and $x=b$, and, continuing positive and finite throughout the interval, let it come to its maximum Y, when $x=\mathrm{X}$. Let v_2 mean the value of the second differential coefficient of $\log\phi x$, when $x=\mathrm{X}$, and assume $\phi x=\mathrm{Y}\epsilon^{-t^2}$. Then

$$\int\phi x\,dx=\mathrm{Y}\sqrt{\left(-\frac{2}{v_2}\right)}\int\epsilon^{-t^2}dt\text{ nearly,}$$

provided that the limiting values of t on the second side are those which, in the equation of $\phi x=\mathrm{Y}\epsilon^{-t^2}$, belong to the limiting values of x taken on the first side. The best approximating cases are as follows:—First, when a and b are the limiting values of x, in which case $-\infty$ and $+\infty$ are those of t, and the result is

$$\int\phi x\,dx\,[a,b]=\mathrm{Y}\sqrt{\left(-\frac{2}{v_2}\right)}.\sqrt{\pi}.$$

Secondly, when the limiting values of x are $\mathrm{X}\pm\xi$, ξ being small. In this case

$$\int\phi x\,dx\,[\mathrm{X}\pm\xi]=\mathrm{Y}\sqrt{\left(-\frac{2}{v_2}\right)}\,2\int\epsilon^{-t^2}dt\left[0,\xi\sqrt{\left(-\frac{v_2}{2}\right)}\right]$$

This method is found, by itself, almost sufficient to meet the wants of the more complicated problems in the theory of probabilities.

Secondly, Fourier's theorem, as it is usually called, by which a discontinuous function can be expressed. This theorem is as follows:—

$$\phi x=\frac{1}{\pi}\iint\cos w(x-v)\,.\,\phi v\,.\,dwdv,$$

from $v=-\infty$ to $x=+\infty$, and from $w=0$ to $w=\infty$. Or thus, the equation

$$\phi x=\frac{1}{\pi}\int_0^\infty\int_{-\infty}^{+\infty}\cos w(x-v)\,.\,\phi v\,.\,\epsilon^{-kw}dwdv$$

is one which, for all values of x, approaches without limit to truth, as k is diminished without limit positively. But if, instead of the limits $-\infty$ and $+\infty$, for v, we write a and b, a being less than b, then

$$\frac{1}{\pi}\int_0^\infty\int_a^b\cos w(x-v)\,.\,\phi vdwdv$$

is a discontinuous function, as follows:—From $x=-\infty$ to $x=a$ exclusive, it is nothing; when $x=a$, it is $\frac{1}{2}\phi a$; from $x=a$ to $x=b$ both exclusive, it is ϕx; when $x=b$, it is $\frac{1}{2}\phi b$; and from $x=b$ to $x=\infty$ it is nothing.

Thirdly, the following methods of expanding a function in series of sines and cosines has been extensively used by Lagrange, Poisson, and Fourier. We give it in the most general form after the manner of Poisson. Let

$$\phi x=\mathrm{A}_0+\mathrm{A}_1\cos\frac{\pi x}{l}+\mathrm{A}_2\cos\frac{2\pi x}{l}+\ldots$$

then, for every value of x from $x=0$ to $x=l$, both inclusive, this equation is true if

$$\mathrm{A}_0=\frac{1}{l}\int\phi vdv\,[0,l],\ \mathrm{A}_m=\frac{2}{l}\int\cos\frac{m\pi v}{l}\,\phi vdv[0,l].$$

Again, the equation

$$\phi x=\mathrm{B}_1\sin\frac{\pi x}{l}+\mathrm{B}_2\sin\frac{2\pi x}{l}+\ldots.$$

is true from $x=0$ to $x=l$, both exclusive, if

$$\mathrm{B}_m=\frac{2}{l}\int\sin\frac{m\pi v}{l}\,\phi vdv[0,l].$$

Further, the equation

$$\phi x=\mathrm{A}_0+\mathrm{A}_1\cos\frac{\pi x}{l}+\mathrm{A}_2\cos\frac{2\pi x}{l}+\ldots.$$

$$+\,\mathrm{B}_1\sin\frac{\pi x}{l}+\mathrm{B}_2\sin\frac{2\pi x}{l}+\ldots.$$

is true for all values of x from $x=0$ to $x=l$, both exclusive (becoming $\frac{1}{2}\phi l$ when $x=l$), if

$$\mathrm{A}_0=\frac{1}{2l}\int\phi vdv[0,l],\ \mathrm{A}_m=\frac{1}{l}\int\cos\frac{m\pi v}{l}\,\phi vdv[0,l]$$

$$\mathrm{B}_m=\frac{1}{l}\int\sin\frac{m\pi v}{l}\phi vdv[0,l].$$

But write $2l$ instead of l, *in the limits only*, or write $[0,2l]$ instead of $[0,l]$, and the equation becomes true for all values of x from 0 to $2l$, both inclusive.

Fourthly, we shall give two cases of the method deduced by Cauchy, as specimens: the complete method itself has some difficulties which are not yet overcome.

First, let ϕx be such a function of x that $\phi(x+y\sqrt{-1})$ vanishes when $x=-\infty$ or $+\infty$, whatever y may be, and when y equals ∞, whatever x may be. For every root of the form $a+b\sqrt{-1}$ (a being either positive or negative, and b being positive, but both finite) which makes ϕx infinite, let $(x-a-b\sqrt{-1})\phi x$ be finite; calculate the value of this last product for each root. For every real root a, of $\phi x=\infty$ ($x=0$ not being one) calculate half the value of $(x-a)\,\phi x$. Let the sum of all these values and half values be P. Then

$$\int\phi xdx[-\infty,+\infty]=2\pi\sqrt{-1}\,.\,\mathrm{P}.$$

Secondly, let ϕx be such a function that $\phi(x+y\sqrt{-1})$ vanishes when $x=+\infty$ or $-\infty$ independently of y, and when $y=+\infty$ or $-\infty$ independently of x. Take the imaginary roots only which make ϕx infinite, and let $(x-a-b\sqrt{-1})\phi x$ be always finite when $a+b\sqrt{-1}$ is one of those roots, and $x=a+b\sqrt{-1}$. Let the sum of all the values of the last product, for the cases in which b is positive, be P; and for the cases in which b is negative let it be Q. Then

$$\int\phi xdx[-\infty,+\infty]=\pi\sqrt{-1}\,.\,(\mathrm{P}-\mathrm{Q}).$$

The subject of definite integrals is one in which the difficulties which have always appeared at the boundaries of mathematical knowledge are constantly met with. The consequence is, considerable difference of opinion about many points. On these, the student who desires to use the higher parts of analysis must hope to form his opinion independently, when his reading and reflection are sufficient for the purpose. Most of these difficulties belong, in principle, to that which accompanies the use of divergent series, which is the most important mathematical question now under discussion. If we were to judge of the future by the past, we should prophesy that divergent series would one day take their undisputed place among well understood objects of analysis, as negative quantities and their logarithms, imaginary quantities and their exponentials, infinitely small quantities with their different orders, discontinuous solutions of differential equations, &c., have successively done, each under a fire of objections which has well served the progress of science, by the defensive researches which it has rendered necessary. It is fortunate for analysis that so many of those who find difficulties propose the entire rejection of the symbols or methods in which the difficulties exist: the proposition excites those who are against any rejection to efforts which they perhaps would not make, if they had only to meet the doubts of allies, instead of the attacks of opponents. That the symbolic expressions of which we are speaking will never vanish out of remembrance, we may confidently predict: of all the points of difficulty of which we have spoken, it may be said, in the words of Horace—

> "Naturam expelles furcâ, tamen usque recurret;"

they will come, and will demand explanation until they get it. They will conquer by numbers, as Fontenelle said the symbol of infinity had done. And it is to be hoped and expected that no difficulty will be completely resolved, without the appearance of a successor, to excite new efforts, and be the stimulating cause of further progress. We should be sorry to think we had arrived at the "last impossibilities[*] of pure mathematics." A very valuable accession to the literature of definite integrals has been recently made by Mr. Bierens de Haan, who has filled the fourth volume of the 'Transactions of the Royal Academy of Sciences of Amsterdam' with a list of definite integrals, with their values, and references to the authors who have given them. The list occupies 550 quarto pages.

INTEGRATION, FINITE. By this term is meant the summation of any number of terms of a series which follows a regular law; and just as INTEGRATION was reduced in a preceding article to the determination of a function from its differential coefficient, so finite integration or summation may be reduced to the determination of a function from its difference. [DIFFERENCE.]

First, let there be a function of x, ϕx, and let x successively become $x+\Delta x$, $x+2\Delta x$ .... up to $x+(n-1)\Delta x$, so that n different values are given to x. It is required to sum the series

$$\phi x+\phi(x+\Delta x)+\phi(x+2\Delta x)+\ldots+\phi(x+\overline{n-1}\Delta x)$$

Let $x=v\Delta x$, and let $\phi(v\Delta x)$ be called ψv. Then the series becomes

$$\psi v+\psi(v+1)+\psi(v+2)+\ldots\ldots+\psi(v+n-1)$$

This sum is a function of n, and such, that if n be changed into $n+1$, one more term $\psi(v+n)$ will be added: consequently it must be the function which has $\psi(v+n)$ for its difference. If, then, we denote the preceding sum by $\Sigma\psi(v+n)$, we find

$$\Delta\left\{\Sigma\psi(v+n)\right\}=\psi(v+n)$$

or Δ and Σ express operations which are inverse to one another. Remark that the symbol Σa does not denote the sum of a number of terms up to a inclusive, but up to a exclusive: thus

$$1+2+3+\ldots\ldots+(n-1) \text{ is } \Sigma n$$
$$1+2+3+\ldots\ldots+(n-1)+n \text{ is } \Sigma(n+1)$$

All that precedes has no reference to the term with which we begin: thus $4+5+\ldots\ldots+n$ and $1+2+3+4+5+\ldots\ldots+n$ are equally denoted by $\Sigma(n+1)$. This symbol is therefore indefinite, but it will be found that the process by which it is to be determined gives an indefinite result.

Suppose, for instance, we have ascertained that $\frac{1}{2}(n^2+n)$ is the function whose difference is $(n+1)$, which will be found to be the case; or

$$\tfrac{1}{2}\left\{(n+1)^2+(n+1)\right\}-\tfrac{1}{2}\left\{n^2+n\right\}=n+1.$$

It is equally true that $\frac{1}{2}(n^2+n)+C$ has $n+1$ for its difference, where C may be anything whatever, provided that it do not change when n changes. Hence

$$\Sigma(n+1)=\tfrac{1}{2}(n^2+n)+C;$$

but a being any whole number less than n, $\Sigma(n+1)$ may stand for $a+(a+1)+\ldots\ldots+n$. Consequently C in the one must be taken in a manner corresponding to a in the other. If n were equal to a, the series would be reduced to one term a, and $\frac{1}{2}(n^2+n)+C$ would become $\frac{1}{2}(a^2+a)+C$. Determine C so that these shall be equal: we have then to make

$$a=\tfrac{1}{2}(a^2+a+C,\ C=-\tfrac{1}{2}(a^2-a)$$
$$a+(a+1)+\ldots\ldots+n=\tfrac{1}{2}(n^2+n)-\tfrac{1}{2}(a^2-a).$$

The inverse method of differences, or that of finite integration, is founded upon the preceding principles and notation: but so far as the mere summation of simple series is concerned, the following rules will be sufficient:—

1. Let a be the first term of a series of n terms, a, b, c, &c. Form the successive differences of a [DIFFERENCE], which will all vanish after a certain point in every instance to which this rule applies. Then the sum of the n terms is

$$na+n\frac{n-1}{2}\Delta a+n\frac{n-1}{2}\frac{n-2}{3}\Delta^2 a+\ldots\ldots$$

EXAMPLE:	1 + 8 + 27 + 64 + 125 + ... + n^3
First diff.	7 19 37 61 ....
Second diff.	12 18 24 ....
Third diff.	6 6 ....
Fourth diff.	0 0 ....

Here $a=1$, $\Delta a=7$, $\Delta^2 a=12$, $\Delta^3 a=6$, $\Delta^4 a=0$, $\Delta^5 a=0$, &c.

and the sum required is

$$n+7n\frac{n-1}{2}+12n\frac{n-1}{2}\frac{n-2}{3}+6n\frac{n-1}{2}\frac{n-2}{3}\frac{n-3}{4}$$

It may be convenient to give the reduction of the preceding formula in the cases where all after the second differences vanish, and the same for the third. Let a', a'', a''', &c., be the differences of a; when $a'''=0$, $a^{\text{iv}}=0$, &c., the sum is one-sixth of

$$a''n^3+(a'-a'')3n^2+(6a-3a'+2a'')n.$$

When $a^{\text{iv}}=0$, $a^{\text{v}}=0$, &c., the sum is one twenty-fourth of

$$a'''n^4+\text{P}n^3+\text{Q}n^2+\text{R}n$$

where $\text{P}=4a''-6a'''$
$\text{Q}=12a'-12a''+11a'''$
$\text{R}=24a-12a'+8a''-6a'''$

2. Let there be a number of terms in uniformly increasing progression, such as 4, $4\frac{1}{2}$, 5, $5\frac{1}{2}$, &c.; and let a series be formed by multiplying a number of terms from the beginning, then the same number from the second, and so on, as in

$$3.4.5+4.5.6+5.6.7+\ldots\ldots+12.13.14$$

To find the sum of this series, put an additional factor at the end of the last term and at the beginning of the first term; subtract the latter from the former, and divide by the common difference of the successive factors taken one more time than there are factors in each term. Thus the sum of the preceding is 12.13.14.15 — 2.3.4.5 divided by 1 taken 4 times. Again

$$1.2+2.3+3.4+4.5+5.6$$

is 5.6.7 — 0.1.2 divided by 1 taken 3 times; or 70; as may easily be verified. Also

$$1.3+3.5+5.7+7.9$$

is 7.9.11 — (— 1) 1.3 divided by 2 taken 3 times; or 116.

3. Let the series consist of reciprocals of terms like the preceding: as

$$\frac{1}{3.4.5}+\frac{1}{4.5.6}+\ldots\ldots+\frac{1}{12.13.14}$$

To sum this series, strike off a factor from the end of the first term and the beginning of the last term; subtract the second from the first, and divide by the common difference of the successive factors taken one time less than there are factors in each denominator. Thus the sum of the preceding terms is

$$\frac{1}{3.4}-\frac{1}{13.14} \text{ divided by 1 taken twice}$$

Similarly $\frac{1}{1.3}+\frac{1}{3.5}+\frac{1}{5.7}$ is $\frac{1}{1}-\frac{1}{7}$ divided by 2 taken once; or $\frac{3}{7}$, as may easily be verified.

INTELLECT (*intellectus*), that which perceives and understands, comprehending all the cognitive powers of the mind, in contradistinction to the active powers or the will. "The internal and immanent acts of the reasonable soul (besides those of common sense, phantasy, memory, passion and appetite, common to man and inferior animals) are intellect and will, and the proper acts of these are intellection, deliberation, and determination, or decision." (Hale's 'Origin of Mankind.') In the Aristotelian philosophy the intellect (νοῦς) first works on the phantasms, and discerns by a spontaneous energy what in many is one, what in things dissimilar is similar and the same (τὸ δὲ ἓν ποιοῦν τοῦτο ὁ νοῦς ἕκαστον). By this means it attains to a new kind of perceptions (εἴδη), more comprehensive than those of sense; and each of these general ideas subsists entire in each individual of an infinite multitude without losing its own unity and permanence. On the other hand it is the source of those primary principles on which all science rests, as conversant about universal and demonstrable truth.

---

[*] These are the words of Mr. A. F. Vogel, of Leipsic, who published in this country a tract on the resolution of all kinds of equations, printed at Leipsic in his own English.

For intellect Mr. Stewart prefers the vernacular term understanding, which he employs in the same extensive signification. But the critical philosophy of Kant distinguishes the intellect into two faculties, understanding and reason. The understanding acting on experience merely compares, judges, and measures its representations, and is conversant solely with their mutual limits and relations, classifying them according to certain schemes of its own which are called categories. While however the understanding is thus limited, the activity of the reason is unbounded, and, as the principle of principles, it is the base and the verification of every special principle and reasoning.

Intellectualism, or intellectual philosophy, as opposed to sensualism, is a particular theory in philosophy, according to which the intellect or thought is the only source of true knowledge, whereas the evidence of sense is but a cheat and delusion. The Eleatæ were the most distinguished adherents of this doctrine. The phrase intellectual knowledge denotes whatever principle or proposition had its origin in the understanding or reason, as opposed to sensuous or empirical knowledge, whose source is sensation. As contradistinguished from sensibles, the objects of this cognition are denominated intelligibles (*αισθητά, νοητά*).

INTERCALARY. [KALENDAR.]

INTERDICT (*Interdictum* in the Roman law). The general distinction between the Roman Interdictum and Actio seems clearly pointed out by Savigny in a few remarks on the passage in Gaius (iv. 139), where that writer treats of the interdict. The words of Gaius, which form the groundwork of the following remarks of Savigny, are: "Certis ex caussis Prætor aut Proconsul *principaliter* auctoritatem suam finiendis controversiis proponit" (or *præponit*, as Haubold reads, after Maffei); and his remarks have reference to the supposed difficulty of the word *principaliter*, and to a certain proposed emendation supported by very indifferent reasons.

The general distinction between the actio and the interdictum is this: in the actio the prætor does nothing, but only allows a *judex*, whose duty it is to inquire and decide. When the *judex* has decided, the matter may in general be considered as at an end, and if the prætor is again called on to act in the cause, such must be viewed as an accidental thing. This appears from the terms of the prætor's order in matters which belong to the actio: he does not command or forbid a thing to be done, but he says "judicium dabo." With the interdictum it is just the reverse. Here also *judices* or *recuperatores* may be required when the facts are in dispute; but as a general rule in matters to which the interdict applies, the case is such that the prætor's order can immediately terminate the question. The prætor accordingly does not say "judicium dabo," but he uses the ordering words "restituas, exhibeas, vim fieri veto," &c.; and this could not be better expressed, as Savigny remarks, than by the words "principaliter," &c.; the meaning of which, as Haubold observes, can hardly be anything else than this: "the prætor or the proconsul at once gives a definitive judgment, by which the dispute, at least for the present, is terminated."

According to Gaius, the general description of the interdictum is this—it ordered something to be done, or forbade something being done. The forms of the orders used on such occasions were called by the general name of interdicta. When the order was to produce something (exhibere), or restore a thing (restituere), the interdicta were called Decreta. The term Interdictum was used when the order forbade a certain thing being done—as disturbing a man who was in possession, *sine vitio*; preventing any trespass on sacred ground, &c.

The general process seems to have been by a kind of bill or petition addressed to the prætor, in which the plaintiff stated his grievance and prayed for redress, that is, for the interdictum. The defendant also stated his case, probably by way of reply to that of the plaintiff. If the case was clear on the part of the plaintiff, he obtained the interdict. Or if the defendant admitted the plaintiff's statement of his case, or if after the interdict was obtained he submitted to its terms, the matter was at an end. If the defendant denied the plaintiff's case, that is, denied that there was any ground for the interdict, or maintained that he had given the plaintiff full satisfaction, and had complied with the terms of the interdict, the plaintiff made his application to the prætor to refer the matter to *judices* or *recuperatores*, or to an *arbiter*. The parties complainant and defendant went before the *judex* or *arbiter* whom the prætor named, and the process then became the usual process of the actio. The parties produced their witnesses and proofs, and the judex or arbiter decided upon them. The terms of the interdict, in case it was prohibitory, were the formal words of the edict which determined in what cases such relief could be given (certis ex caussis), only so far varied as to apply to the parties who were in dispute. In the restitutory and exhibitory interdict, the terms of the order would necessarily vary according to circumstances. If the matter came before a *judex*, the only question as to the prohibitory interdict which he had to settle was, whether the defendant had, by his acts, brought himself within the prætor's interdict. If he had, the interdict must be enforced against him; if not, it must be dissolved. In the case of the restitutory and exhibitory interdict coming before the *judex* or *arbiter*, the matters for inquiry would be—whether the defendant had, by his acts, given good ground for the interdict; whether he had satisfied the terms of the interdict; what damages the defendant should pay to the plaintiff, in case he had not satisfied the terms of the interdict, or had only satisfied them imperfectly. If no *sponsio* (deposit of money by the parties abiding by the result of the inquiry) had been entered into, and consequently the matter had come before an *arbiter*, all these three points had to be determined, and the damages were at the discretion of the *arbiter*; in case there was a sponsio (which in the prohibitory interdict was necessary, but in the other interdicts not absolutely necessary), the *judices* or recuperatores had to determine only the first two points. (Cicero, 'Pro Cæcina,' 8.) In fact, when the matter came before a *judex* or *arbiter* the interdict process did not differ from that of the ordinary actio, as appears from Cicero's oration 'Pro Cæcina,' in which the plaintiff Cæcina had obtained the prætor's interdict 'Unde Tu,' &c., against the defendant Æbutius, and the matter had been referred to recuperatores. The defence of Æbutius before the recuperatores was, that he had obeyed the interdict and had restored the plaintiff to the same place from which he had ejected him. The defendant had not in fact done this; but it appears to have been sometimes the formal way of raising the question, whether the act complained of had been committed. If it was not committed, the defendant had in substance obeyed the interdict, that is, had not acted contrary to it. Mr. Spence, in his work on the 'Equitable Jurisdiction of the Court of Chancery,' has given a short account of this branch of the Roman law of procedure; and in that part of his book where the history of the rise and progress of the English chancellor's jurisdiction by injunction is discussed (vol. i., ch. xxii.), he maintains that the Roman jurisprudence afforded a model from which a system might be constructed that should supply the desired means for protecting property against actual or prospective dangers. But as he shows, the application of the principle thus introduced was extended much beyond the limits of the Roman process, and the clerical chancellors and their lay successors gradually made great improvements in the method of carrying out the system they had thus introduced.

The authorities for what is above stated are: Haubold, *Ueber die Stelle von den Interdicten in den Veronesischen Handschriften*; and Savigny, C., *Nachträgliche Bemerkungen*, in the *Zeitschrift für geschichtliche Rechtswissenschaft*, Ser band. For the application of the interdict to the case of possession, Savigny, *Das Recht des Besitzes*, translated into English by Sir Erskine Perry (book iv.), should be consulted, and his remarks on the case of Cæcina. And in Niebuhr's *History of Rome*, English translation, edit. 1851, vol. ii., p 180, the reader will find a very able sketch of this intricate and obscure part of Roman legal history. The valuable work of Brissonius, *De Formulis*, lib. v., c. 154, contains a collection of passages which refer to the functions of the judex in the interdict process; and for the actual text of the Roman law on this subject the reader is referred to the *Commentaries of Gaius*, iv., § 138; Justinian's *Institutes*, book iv., title 15, § 170; and *Digest*, book xliii. [INJUNCTION.]

INTERDICT, in the law of Scotland, is a proceeding in the nature of an injunction from a court of equity in England. It is a prohibitory order, forbidding some act from being done, and it is obtained on the application of the party who would be injured by the performance of the act. It may be issued by the Court of Session, or by the Sheriff's Court. Interdicts also occupy in the law of Scotland a place analogous to the writ of prohibition in England. They are frequently obtained for preventing inferior courts, or courts of limited operation, from exceeding their jurisdiction. To this end the form has been frequently adopted in the disputes between different parties in the Church of Scotland. In pressing matters, interim interdict is awarded before the parties are heard, but in the general case intimation is given to the other party, who gives in answers, and the matter proceeds as an ordinary litigation.

INTERDICT, ECCLESIASTICAL, a mode of censure employed at times by the Roman Catholic church, by which, in consequence of some offence alleged to have been committed by the people or rulers of a town or country, the pope forbade by a bull the performance of any kind of church rites within the same; the church-service was suspended, the sacraments were not administered, and the funeral service was not read. The use of interdicts appears to have originated with the bishops of the 9th century. Hincmar, bishop of Laon in France, laid a parish of his diocese under an interdict in the year 870. (Moreri's 'Dictionary,' art. 'Interdict.') In the middle ages this measure was often resorted to by the popes in consequence of some serious dispute with the sovereigns of particular countries, and it had the effect of throwing whole kingdoms into consternation, and even into a state of rebellion, by which the refractory sovereigns were obliged to sue for pardon from the pontiff. Gregory VII. and Innocent III. made free use of the interdict. Adrian IV. laid Rome itself under an interdict for the purpose of driving away Arnaldo da Brescia and his followers. Some popes mitigated the rigour of the interdict out of regard to the spiritual wants of the people, who could not be justly punished for the guilt of their rulers. Gregory IX., during the interdict against Frederic II., allowed mass to be said on Sundays. On some occasions the sacrament to the dying and baptism to infants were allowed to be administered. (See Lyndwood.)

The frequent abuse of the interdict has been censured even by Roman

Catholic writers. In course of time the measure was found no longer to answer its object, and it became of rare occurrence. Paul V., in April, 1606, laid the republic of Venice under an interdict, because the senate had decreed that no more convents should be founded, and no more property should be bequeathed to monastic orders without permission from the government. The senate forbade the bull of interdict to be published in the territories of the republic, and ordered the parochial clergy to continue the exercise of their sacred ministry as usual. The Jesuits, Franciscans, and other monks pleaded their duty of obedience to the see of Rome, and the senate told them that they might depart, which they did. At last, in 1607, through the mediation of Henry IV. of France, the pope removed the interdict, which had produced little or no effect on the minds of the Venetian people.

INTEREST, money which is paid for the use of other money, the lender stipulating for a fixed sum to be paid yearly, half-yearly, or quarterly, for each 100*l.* lent, until the money is returned. When this is not the case, and when the money paid for the loan depends upon the success of an undertaking, or any casualty not connected with the duration of life, it is called a *dividend;* when the money and its interest are to be returned by yearly instalments, and paid off in a certain fixed number of years, it is called an *annuity certain;* but when the payment is to depend upon the life of any person or persons, it is called a *life annuity.* [ANNUITY.] But by whatever name the proceeds of money may be called, the rules of calculation are the same in every case but that of a life contingency.

A simple rule for converting shillings, pence, and farthings into the decimal of a pound, alluded to in the article ANNUITIES, might be made of such frequent use in calculations connected with interest, that we begin with it. The rule is founded upon the circumstance of one farthing being very little more than the thousandth part of a pound.

To convert any number of shillings, pence, and farthings to the decimal of 1*l.*, as far as three places.

RULE.—Allow 100 for every two shillings, and 50 for the odd shilling, if there be one, and a unit for every farthing in the pence and farthings, adding 1 if the pence and farthings be sixpence or upwards. Then make three decimal places of the result. Thus, 1*s.* 7¾*d.* give 50 and 31 and 1, or 82, which, converted into a decimal of three places, is ·082, or 1*s.* 7¾*d.* is ·082*l.*: the truth lies between ·0822 and ·0823. Again, 17*s.* 4½*d.* give 800 and 50 and 18, or ·868, so that 17*s.* 4½*d.* is ·868*l.* very nearly.

To convert any decimal of a pound of three places into shillings, pence, and farthings.

RULE.—Take away the decimal point, and make a whole number of the three places: for every 100 of this whole number allow two shillings, and another shilling to the remaining 50, if so much remain. Let every unit of the remainder be one farthing, but strike off one if the remaining number exceed 24. Thus, ·973*l.* gives 18*s.* and 1*s.* and 23 farthings, or 19*s.* 5¾*d.*; but ·147*l.* gives 2*s.* and 46 farthings, or 2*s.* 11½*d.* The following are examples of both rules:—

6¾*d.* is ·028*l.*	16*s.* 0½*d.* is ·802*l.*
3*s.* 2*d.* is ·158*l.*	17*s.* 11*d.* is ·895*l.*
4*s.* 9¼*d.* is ·238*l.*	19*s.* 10½*d.* is ·993*l.*

This rule may be completed, so as to give any number of places, as follows:—For the fourth and fifth places of decimals, allow 4 for every farthing above the last sixpence, with a unit additional for every six farthings. Thus, for 2*s.* 5½*d.*, the first three places being ·122, the fourth and fifth places are found by 22 × 4 + 3, or 91. For the sixth and all following places, take the number of farthings above the last three halfpence for a numerator, 6 for a denominator, and form the figures of the corresponding decimal fraction. In the above instance we have ⅔, or ·6666 ...., whence 2*s.* 5½*d.* is ·122916666*l.* ....

Interest is usually reckoned by the sum paid yearly for each 100*l.*; thus, 4 *per centum*, abbreviated into 4 *per cent.*, means that 4*l.* is paid yearly for 100*l.*, or that $\frac{1}{25}$th of the whole sum is paid yearly for its use. In some cases, as in the dividend of a bankrupt's estate, a part is compared with the whole by stating how much of each pound is paid. The preceding rule gives the means of reducing one to the other instantaneously: thus, since 4*s.* 9¼*d.* is ·238*l.*, a bankrupt who pays the former sum per pound, or ·238*l.* for 1*l.*, pays 23·8*l.* for each 100*l.*, or 23⅘ per cent. Similarly, 37⅕ per cent., or 37·2*l.* for 100*l.*, is ·372*l.* for 1*l.*, or 7*s.* 5½*d.* in the pound.

Interest is called *simple* when it is paid as soon as due, or when, if deferred, interest is not charged upon interest. But when the latter charge is made, the interest is called *compound.* In simple interest it makes no difference whether it be payable yearly or at shorter terms; but this is not the case in compound interest. The sum lent is called the *principal;* and the principal, together with the interest, the *amount;* also, the principal is called the *present value* of the amount.

A common question of simple interest requires merely the process of taking a given fractional part of a sum of money, and need not be explained at length in a work of reference. One example, however, will serve to show the facilities which the preceding rule affords.

What is the interest upon 697*l.* 13*s.* 4½*d.*, at 4½ per cent., for 7¾ years?

To find this, we must take the hundredth part of the sum 4½ times for one year's interest, which we must then repeat 7¾ times.

£697 13*s.* 4½*d.* is £697·668

£697·668

7·84877	243·31171
243·31172	

Answer £243·312 or £243 6*s.* 3*d.*

When interest is to be taken for a number of days, a person who is often required to perform the operation will provide himself with a set of tables, several of which are published. Those who do not often meet with the operation must take such a fraction of a year's interest as the number of days in the question is of a year. The following rule will facilitate the introduction of the arithmetical rule of practice:—

RULE.—Whenever the portion of an amount per annum is to be taken corresponding to a number of days, calculate as if the year had only 360 days, and from the result subtract its 72nd part, or one farthing in 1*s.* 6*d.*, or 3½*d.* on each guinea. This falls short of the truth by about 1*d.* in 20*l.* Thus, suppose the yearly interest is 283*l.* 17*s.* 4*d.*, and that for 254 days is required—

		283·866
180	½	141·933
60	⅓	47·311
12	⅕	9·462
2	⅙	1·577
		8)200·283
		9) 25·035
		2·782
		200·283
		197·501

Answer, 197*l.* 10*s.*;—or, adding 1*d.* for each 20*l.*, about 197*l.* 10*s.* 10*d.*, which is within one halfpenny of the truth.

It is sometimes necessary to express the interest by the day, in which the following rules will be convenient:—

To turn a given amount per day into the corresponding amount per year, to the number of pence per day add its half, and take as many pounds as there are now pence. This is the amount in 360 days, and five days' allowance added gives the result.

To find out how much a sum per annum yields per day, subtract one-third from the pounds, and take as many pence as there are in the result. The answer is the preceding result diminished by one farthing in 1*s.* 6*d.*, or its 72nd part.

Thus, 3¾*d.* per day, or 3·75 pence, gives 3·75 + 1·875, or 5·625 per 360 days, which is 5*l.* 12*s.* 6*d.* To this add five times 3¾*d.*, or 1*s.* 6¾*d.*, which gives 5*l.* 14*s.* 0¾*d.* per annum.

Again, 26*l.* 14*s.* 7*d.* per annum, or (nearly enough) 26·7*l.*, gives 26·7—8·9 pence per day nearly; that is, 1*s.* 5¾*d.* Diminish this by one farthing, and 1*s.* 5½*d.* is the answer within a farthing.

All persons who attempt for the first time to use decimal fractions in money computations imagine that they gain nothing; but a little practice soon convinces them of the contrary.

We now proceed to the subject of compound interest, which cannot be satisfactorily treated without algebra. Let r be the interest of 1*l.* for one year, or $100\,r$ the rate per cent. As follows:—

At 2¼ per cent. $r = {\cdot}0225$	At 4 per cent. $r = {\cdot}04$
At 3½ per cent. $r = {\cdot}035$	At 5⅛ per cent. $r = {\cdot}05125$.

It is not usual in treating of compound interest to separate that part of the amount which is interest from the whole. We shall, therefore, speak only of principal and amount, or, when the latter is the given sum, of present value and deferred principal. Hence, $1 + r$ is the amount of 1*l.* in one year, $2 + 2r$ that of 2*l.* in one year, and, generally, a sum which is a pounds at the beginning of any one year becomes $a(1 + r)$ pounds at the end.

Consequently, the amounts of 1*l.* at the end of one, two, three, &c., years, are $1 + r$, $(1 + r)^2$, $(1 + r)^3$, &c., pounds; and 1*l.* at the end of n years becomes $(1 + r)^n$ pounds. If, then, £a becomes £A in n years, at r per pound, we have

$$A = a\,(1 + r)^n \qquad a = \frac{A}{(1 + r)^n}$$

$$r = \sqrt[n]{\frac{A}{a}} - 1 \qquad n = \frac{\log A - \log a}{\log (1 + r)}$$

from one of which forms of the equation, either of the four, A, a, r, or n, can be found, when the other three are known.

From the second form it appears that the fraction of 1*l*., which will in a year amount to a pound, is 1 divided by $1 + r$. Let this be called v; we have then

$$v = \frac{1}{1+r} \qquad r = \frac{1-v}{v}$$

Hence it is easily seen, that according as a pound is to be the amount at the end of one, two, three, &c., years, the principal now necessary to produce that amount is v, v^2, v^3, &c., or v^n expresses "the present value of 1*l*. to be received at the end of n years." Here are no less than *fifteen* words necessary to express a fundamental result; and when we speak of $(1+r)^n$ it must be as "the amount of 1*l*. in n years." To shorten these phrases, the former might be advantageously called the nth present value, and the latter the nth amount.

The sum which yields 1*l*. every year is called the value of a perpetuity of one pound, or simply the *perpetuity* of 1*l*. If it be P, we have

$$\text{P}r = 1, \text{P} = \frac{1}{r}, r = \frac{1}{\text{P}}, \text{P} = \frac{v}{1-v}, v = \frac{\text{P}}{1+\text{P}}.$$

The reader will find an arithmetical account of ANNUITIES under that word; we now proceed to the algebraical formulæ connected with them. An annuity, and also a perpetuity, is always said to be created a year before any payment is made: thus an immediate grant of an annuity payable yearly implies that the first payment is made a year hence; and similarly of a perpetuity. But in cases where we have to speak of an annuity or perpetuity, of which one payment is to be made now, we propose to call them an annuity due, and a perpetuity due. Again, an annuity or perpetuity deferred for, say 10 years, makes its first payment in 11 years: but a perpetuity due in 10 years, makes the first payment at the end of 10 years. An annuity of 20 years makes 20 payments; an annuity due of 20 years makes 21 payments. Let all annuities mentioned be of 1*l*., unless otherwise specified.

The present value of an annuity for n years is evidently

$$v + v^2 + v^3 + \ldots + v^{n-1} + v^n$$

for v in one year becomes 1*l*., and provides for the first payment; v^2 for the second, and so on. The preceding is equivalent to

$$\frac{v - v^{n+1}}{1-v} \quad \text{or} \quad \frac{1-v^n}{r} \quad \text{or} \quad \frac{(1+r)^n - 1}{r(1+r)^n}$$

Similarly the present value of an annuity due for n years is 1*l*. more than the preceding, or

$$\frac{1 - v^{n+1}}{1-v} \quad \text{or} \quad \frac{1+r-v^n}{r} \quad \text{or} \quad \frac{(1+r)^{n+1} - 1}{r(1+r)^n}$$

TABLE I.

THE PRESENT VALUE OF £1, DUE AT THE END OF ANY NUMBER OF YEARS.

100	36·61411	31·59891	27·65543	24·50500	21·94985	19·84791	16·61755

An annuity of n years deferred for k years is now worth

$$v^{k+1}+v^{k+2}+\ldots\ldots+v^{k+n}$$

$$\text{or } v^k\frac{v-v^{n+1}}{1-v} \quad \text{or} \quad \frac{v^k-v^{n+k}}{r} \quad \text{or} \quad \frac{(1+r)^n-1}{r(1+r)^{n+k}}$$

A perpetuity deferred for k years is worth $\frac{v^k}{r}$ or $v^k P$; but a perpetuity due in k years is the same as a perpetuity deferred for $k-1$ years, and $k-1$ must be written for k in the preceding; giving $v^{k-1}P$.

If the proceeds of an annuity of n years be put out to interest as fast as they become due, then at the instant after the last payment is made the first payment will have improved for $n-1$ years, the second for $n-2$ years, &c., and the last payment will have made nothing: whence the whole amount of the annuity at the moment of expiration is

$$(1+r)^{n-1}+(1+r)^{n-2}+\ \ldots\ldots\ +(1+r)+1$$

$$\text{which is } \frac{(1+r)^n-1}{r} \quad \text{or} \quad \frac{1-v^n}{rv^n}$$

The annuity of n years, which 1*l.* will buy, makes at each payment $r \div (1-v^n)$; and so on: that is, the following are methods of restoring 1*l.* now lent:—

1. By annuity for n years . . . . of $\frac{r}{1-v^n}$
2. By annuity for n years, deferred k years, of $\frac{r}{v^k-v^{n+k}}$
3. By perpetuity . . . . . . of r
4. By perpetuity deferred for k years . . of $\frac{r}{v^k}$

And 1*l.* due at the end of n years, may be paid by an n years annuity of $rv^n \div (1-v^n)$, or by an annuity due of $rv^n \div (1+r-v^n)$.

It is hardly necessary to say, that an annuity, &c., of £s is to be found by multiplying the annuity, &c., of 1*l.* by s.

An annuity of n years, which gives 1*l.* at the first payment, 2*l.* at the second payment, &c., and £n at the nth and last payment, is worth

$$\frac{v+nv^{n+2}-(n+1)v^{n+1}}{(1-v)^2}$$

and when the numerator and denominator change places, we have the fraction of 1*l.*, which must be paid at the end of the first year, in order to repay 1*l.* now lent, by uniformly increasing instalments in n years.

An annuity of n years, which gives £n at the first payment, £$(n-1)$

TABLE III.

THE ANNUITY WHICH £1 WILL PURCHASE FOR ANY NUMBER OF YEARS.

at the second payment, &c., and 1*l.* at the *n*th and last payment is worth

$$\frac{nv + v^{n+2} - (n+1)\,v^2}{(1-v)^2}$$

and, reversing numerator and denominator, we have the fraction of 1*l.*, which must be paid at the end of the first year, in order to repay 1*l.* now lent, by uniformly decreasing instalments in *n* years.

All the preceding formulæ are easy to compute by aid of logarithms, and the result of any one being given, and the rate of interest, it is easy to determine (except in the two last formulæ) the number of years necessary. But if the number of years be given, and the result, and it is the rate of interest which is unknown, an equation must be solved, the degree of which is at least as high as the number of years.

When the interest is to be paid at the expiration of a fraction of a year, it is the same thing as if a less rate of interest were paid for a greater number of years. In the preceding investigations $1 + r$ may be considered as the amount of 1*l.* at the end of a term, and *n* as the number of terms. If then quarterly interest be paid during *n* years, *r* per pound per annum gives $\frac{1}{4}r$ per pound per quarter, which continued for $4n$ quarters gives $(1 + \frac{1}{4}r)^{4n}$ for the amount.

The tables appended to this article are intended to save the trouble of calculation in ordinary cases. They extend from 2½ to 6 per cent. Higher rates are occasionally useful, but it is to be remembered that when the rate of interest is high, and the number of years not small, tables of yearly interest become sensibly incorrect when the money is really improved half-yearly or quarterly. Thus the tables at 5 per cent., with double the number of terms, will better represent the actual progress of money at 10 per cent. than the common yearly tables. The calculator who wishes to meet every case with readiness, must make himself independent of particular tables. This can be done with the common seven-decimal tables of logarithms, up to five places of decimals and 100 years: and if the logarithm of $1 + r$ be given to ten places of decimals, up to seven places and 1000 years. The following subsidiary table is therefore given, which contains the logarithms of $1 + r$, for every quarter per cent. up to 6 per cent., and to ten places of decimals. (See INTERPOLATION for a simple method of finding intermediate logarithms.)

$1+r$	Log. $(1+r)$	$1+r$	Log. $(1+r)$
1·0025	·00108 43813	1·0325	·01389 00603
1·0050	·00216 60618	1·0350	·01494 03498
1·0075	·00324 50548	1·0375	·01598 81054
1·0100	·00432 13738	1·0400	·01703 33393
1·0125	·00539 50319	1·0425	·01807 60636
1·0150	·00646 60422	1·0450	·01911 62904
1·0175	·00753 44179	1·0475	·02015 40316
1·0200	·00860 01718	1·0500	·02118 92991
1·0225	·00966 33167	1·0525	·02222 21045
1·0250	·01072 38654	1·0550	·02325 24596
1·0275	·01178 18305	1·0575	·02428 03760
1·0300	·01283 72247	1·0600	·02530 58653

By taking the first nine multiples of any one of these logarithms, a table of seven places might be formed, which should be correct in every figure. The following, for instance, is the table for 1 per cent. per quarter, or 4 per cent per annum, payable quarterly :—

1	·0043214	10	·0432137	100	0·4321374
2	·0086427	20	·0864275	200	0·8642748
3	·0129641	30	·1296412	300	1·2964121
4	·0172855	40	·1728550	400	1·7285495
5	·0216069	50	·2160687	500	2·1606869
6	·0259282	60	·2592824	600	2·5928243
7	·0302496	70	·3024962	700	3·0249617
8	·0345710	80	·3457099	800	3·4570990
9	·0388924	90	·3889236	900	3·8892364

For instance, suppose it required to find out in how many years money will increase tenfold at 4 per cent. payable quarterly : or to solve the equation $(1{\cdot}01)^{4n} = 10$.

$$\begin{array}{rl} \text{Log. } 10 = 1{\cdot}0000000 & \\ {\cdot}8642748 & \ldots\ 200 \\ \hline {\cdot}1357252 & \\ {\cdot}1296412 & \ldots\ \ 30 \\ \hline {\cdot}0060840 & \\ {\cdot}0043214 & \ldots\ \ \ 1 \\ \hline {\cdot}0017626 & \end{array}$$

Answer.—The amount of 1*l.* in 232 quarters, or 58 years, will be a little more than 10*l.*

We now describe the tables which follow :—

Table I. gives the present value of 1*l.* to be received at the end of the several years marked. Thus, in the column of 4 per cent. opposite to 15 years, we find ·55526, which is the sum that will in fifteen years, at 4 per cent., amount to 1*l.* The present value of 100*l.* similarly circumstanced, is 55·526*l.* or 55*l.* 10*s.* 6½*d.*

Table II. gives the present value of an annuity of 1*l.* Thus opposite to 20 years in the column of 5 per cent. is 12·46221, meaning that 1*l.*, to be paid at the end of every year from this time for 20 years, is now worth 12·46221*l.*, if money will make 5 per cent.

Table III. shows the annuity which 1*l.* will buy for any number of years. Thus in the column of 4 per cent., opposite to 7 years, we find ·16661. If then 100*l.*, now lent, were to be repaid by instalments in seven years, the first instalment a year hence, so as to allow compound interest at 4 per cent., then each instalment should be 16·661*l.*

Table IV. gives the amount of 1*l.* improved at compound interest during a number of years. Thus opposite to 11 years in the column of 3 per cent. is found 1·38423, meaning that 1*l.* in 11 years, at 3 per cent., amounts to 1·38423, and 100*l.* to 138·423*l.*

Table V. gives the amount of an annuity of 1*l.*, as it will be the moment after the last payment has been made, if the preceding payments have been allowed to accumulate. Thus in the column of 3½ per cent., under 27 years, we find 43·75906, so that the proceeds of an annuity of 100*l.* for 27 years, allowed to accumulate at 3½ per cent., will at the last payment have realised 4375·906*l.*

The following equations show easy means of verifying any one of these tables by another. Let I, II, III, IV, V, represent the results of the five tables for some one number of years, and rate of interest. Then

$$\mathrm{I} \times \mathrm{IV} = 1 \qquad \mathrm{I} + r \times \mathrm{II} = 1$$
$$\mathrm{II} \times \mathrm{III} = 1 \qquad \mathrm{IV} - r \times \mathrm{V} = 1$$

Interest, as payable upon a debt not discharged on the day it becomes due, is unknown to the Common Law, payment of such interest being still rather the exception than the rule. Some debts it is true carry interest by the custom of merchants or traders, being those constituted by bills, and since the statute of Anne, by promissory notes. But unless there is an express agreement to such effect between the parties, debts do not carry interest at all. This uncommercial rule of law led to the statute 3 & 4 Will. IV., c. 42, which enables a jury, if they think fit, upon all debts or sums certain, to allow interest to the creditor, at a rate not exceeding the current rate of interest, from the time when such debts or sums were payable, if payable by virtue of a written instrument at a certain time; or if payable otherwise, then from the time of a demand of payment in writing, so as such demand give notice that interest will be claimed from the date of such demand. This statute also empowers juries to give damages, in the nature of interest, in respect of the detention or appropriation of goods. By 1 & 2 Vict., c. 110, judgment-debts carry interest at the rate of 4 per cent. per annum from the time of entering up the judgment. Legacies are payable at the end of one year after a testator's death, and from the end of that year carry interest at the rate of 4 per cent. per annum; unless the testator has made special provisions in his will as to the time of payment and the rate of interest. See farther, ANNUITY, BOTTOMRY, USURY.

INTERFERENCE is a term used to express the mutual influence of two streams of light, or series of pulsations of sound, or, generally, two series of vibrations of any kind. The term is most commonly employed with reference to light.

We owe to Dr. Young the discovery of the grand principle of the interference of light, and the explanation thereby, in the most simple and satisfactory manner, of various phenomena of which no rational account had previously been given.

The principle itself, when considered merely as embodying the phenomena which belong to it, may be thus stated. When two streams of light from the same source, after traversing paths very slightly differing from each other in length, mix together, crossing at a small angle, they partially or completely neutralise each other's effect, or else strengthen each other, according to the difference of path. When the two interfering streams are of equal intensity the neutralisation is complete, and we have realised the apparent paradox of two lights producing darkness. The law which determines whether the illumination due to this joint action of the two streams is a maximum or minimum is this: When the difference of the two paths (both being supposed to be in air) is zero, or an even multiple of a certain fundamental constant, the illumination is a maximum, when an odd multiple it is a minimum. This fundamental constant depends only on the refrangibility of the light, and decreases in magnitude from the red to the violet end of the spectrum. When the incident light is white, the light of each particular degree of refrangibility of which it is composed presents the phenomena of interference independently of the light of other refrangibilities; and the precise circumstances of the interference being determined by the value of the fundamental constant belonging to the particular kind of light, a value which, as we have seen, changes from one colour to another, a maximum of illumination as regards one part of the spectrum may coincide with a minimum of illumination as regards another. Thus, alternations of colour are observed, and not merely alternations of intensity, and by the time the difference of path amounts to that belonging to the 7th or 8th maximum for mean rays, the colours are so mixed, that the result is sensibly white light of uniform intensity; though, if the interfering light is subjected to prismatic analysis, the interference may be traced up to a difference of path amounting to many thousand times the value of the fundamental constant.

The idea we attach to the fundamental constant depends on the notion we form of the nature of light. The theory of undulations alone affords a simple and clear explanation of the phenomena of interference, and is competent to meet the demands of the science of optics in its present state. According to this theory, the two streams consist of two perfectly similar series of undulations propagated in the "ether," of which in this theory the existence must be assumed. According to the general dynamical principle of the coexistence of small motions, the disturbance which one series will produce in the ether will be sensibly the same, whether that portion of ether be or be not agitated by the other series. If the lengths of path be equal, the front of the same wave belonging to each series will arrive at the same moment at the same point of the ether, and the displacement of the particle will be the sum of those due to the series taken separately. The same will still be the case if one series be in advance of the other by one, two, or any exact number of wave's lengths. If, however, one series be in advance of the other by just half a wave's length, or any odd multiple of half a wave's length, the displacements simultaneously produced in the ether by the two series respectively will always be in opposite directions, and the actual displacement will be only the difference of the two displacements, or zero in case the two are equal, —that is, in case the two streams are of equal intensity. In this way the phenomena of interference admit of the simplest explanation; in short, the fact of interference, as well as its laws, might have been predicted from the fundamental principles of the undulatory theory. The fundamental constant above mentioned evidently represents half the length of a wave of light.

If a portion of the path of either stream lie in glass, or other refracting medium, since according to the undulatory theory the velocity of propagation is slower in such a medium than in air, in the ratio of the refractive index to unity, it follows that the interference must take place as if the stream had described a longer path in air in the above ratio. This agrees with observation.

The laws of interference were applied by Dr. Young to the explanation of the colours of thin plates, and to various phenomena of diffraction [DIFFRACTION], and come into incessant use in the explanation of the phenomena of light. It will be sufficient here to mention a fundamental experiment of Fresnel's, which is easily repeated. Its fundamental character depends upon the circumstance, that in this case the interfering streams neither graze the edge of diffracting bodies, nor are reflected from thin plates, but simply from two ordinary mirrors.

Take two pieces of plate glass, 3 or 4 inches each way, having each a clean edge (that is, pretty free from chipping), and varnish the backs so as to stop the reflection from the second surface. On a block of wood place 6 balls of kneaded wax, and on the balls place the pieces of glass, with their clean edges in contact, so that each piece rests on three balls. By pressing on the balls adjust the mirrors so that their planes make a blunt angle, pointing inwards, of say 179½°. Great care must be taken that neither piece juts out above the other, as the experiment will fail if the mathematical line of intersection of the planes of the mirrors is much removed from the edges in contact. A little jutting is easily got rid of by gently squeezing the wax. Now reflect the sun's light into a darkened room, passing it through a lens of short focus (suppose $\frac{1}{4}$ inch) placed in the window. A second lens may be added at a little distance in case the focal length of the first lens be not short enough to give a sufficiently small image of the sun. Let the light diverging from the image of the sun be reflected, at the distance of a few feet, from the mirrors, at any convenient angle, and at the distance of a few feet from the mirrors examine with a lens the doubly bright portion of the field where the two reflected streams mix. This will be seen traversed by a series of fine bands, called *fringes of interference*, alternately bright and dark near the middle fringe, and coloured on receding from the middle. They are readily distinguished from the vague fringes seen at the edges of the doubly illuminated portion of the field by the blackness of the minima near the centre of the system, and also by their position, as they are always perpendicular to the line joining the two virtual images formed by the light reflected from the two mirrors respectively, and therefore run obliquely across the doubly illuminated portion of the field when the mirrors are adjusted so that the line of intersection of their planes is oblique to the edges in contact. Instead of the mirrors Fresnel used also a flat prism with a very obtuse angle, the fringes in this case being formed by the transmitted light.

The explanation of these fringes follows at once from the principle of interference. The length of the path of either reflected stream is the same as if the light came from the corresponding virtual image of the luminous point. We may suppose therefore that we have two perfectly similar series of waves starting simultaneously from the two virtual images respectively (which we may call I, I'), and mixing within the wedge-shaped portion of space where the reflected streams cross. Any point of a plane bisecting $I\,I'$ at right angles will be equidistant from I and I', and therefore at any such point the two streams will conspire, and that for light of all colours. For any particular kind of light the two streams will again conspire at a point whose distances from I, I' differ by λ, 2λ, 3λ, &c., λ being the wave-length for that kind of light. The locus of such a point will evidently be a hyperboloid generated by the revolution round $I\,I'$ of a hyperbola having I, I' for its foci, and λ, 2λ, 3λ, &c., for its transverse axis. Along the intermediate hyperboloids whose transverse axes are $\frac{1}{2}\lambda$, $\frac{3}{2}\lambda$, &c., the two streams will be in perfect opposition, and will completely neutralise each other. On account of the excessive smallness of λ (which varies from about the one forty-thousandth to the one sixty-thousandth part of an inch in passing from the red to the violet), a section of these hyperboloids by a small plane at the focal distance of the eye-lens will not sensibly differ from a series of equidistant lines parallel to the plane first mentioned. Hence any one kind of light forms a system of parallel bands alternately bright and dark, but the scale of the system decreases from the red to the violet, so that beyond a moderate distance from the central bright fringe, which is common to all the colours, the fringes obliterate each other by overlapping.

We have seen that the phenomena of interference are by no means confined to light. The *beats* for instance heard when two musical notes are very nearly but not exactly in unison, are a phenomenon of interference of sound. For the description of a very elegant experiment rendering the interference of sound a matter of ocular inspection, the reader is referred to a paper by Mr. Hopkins, published in the 5th volume of the 'Transactions of the Cambridge Philosophical Society,' p. 257.

INTERJECTIONS have been defined to be "words used to express some passion or emotion of the mind," as exclamations of joy, grief, astonishment, &c. Interjections however can hardly be considered as a distinct part of speech, but are more properly natural sounds common to all men when laughing, in pain, &c. Many words, such as *malum, macte, profecto*, &c., in Latin, and *adieu, welcome*, &c., in English, which have been considered as interjections by grammarians, ought to be regarded as verbs, substantives, adjectives, or adverbs.

INTERLOCUTORY (*inter*, between, and *loquor*, to speak) a term applied to those judgments, decrees, and orders of courts of law and equity which are made in the progress of a suit before final judgment. Thus, orders for the production of papers, for taking an account of the dealings out of which the dispute arises, are interlocutory orders or decrees. Those judgments which, though they establish the right of the plaintiff, leave the amount of damages to be ascertained by a jury, are generally, but incorrectly, termed interlocutory judgments.

INTERLUDE, a brief piece of church music for the organ, seldom exceeding a few bars, generally produced *ex tempore*, and played after each stanza, except the last, of the metrical psalm. This, being merely for the purpose of giving breathing time to the singers, should always be short and grave, and in keeping with the psalm tune.

Interlude is also the name for a stage-play, among the earliest of the productions of English dramatic literature. It belonged originally to the class of "moralities," and John Heywood, in the time of Henry VIII., was the first to free it from allegorical materials. In modern times the name has been still further extended, and is often applied to a short dramatic piece performed between two others.

INTERMENT, the burial of a dead body in the earth. The manner of disposing of the bodies of the dead has varied in different nations; but the most general modes have been interment in the earth and burning on a funeral pile. The practice of burying is probably the oldest mode, and with most nations has been the ordinary mode of sepulture; but the custom of burning the body, and afterwards collecting the ashes and depositing them in a tomb or urn, became very general among the Greeks and Romans. Among the Greek nations, however, both the burning of the dead and the interment of dead bodies in the earth were practised. The Romans in the earlier periods of their history certainly buried their dead. It is recorded that Sulla was the first member of the Cornelia gens who was burnt. The Egyptians do not seem to have ever adopted the practice of burning the dead; and though, as we have observed, burning became common among the Greeks and Romans, it seems that interment was always practised by the lower orders among the Romans. At Rome, bodies were sometimes buried in pits (puticuli), or thrown to decay in certain unfrequented places. (Varro, 'De Ling. Lat.' v. 25; Horace, 1, Sat. v. 8, &c.) Tacitus (xvi. 6) speaks of the embalming and interment of Poppæa, the wife of Nero, as a deviation from the general practice. The practice of burning the dead appears to have gradually gone into disuse under the Empire: and probably it was never practised by the Christians.

A constitution of the Emperor Justinian (A.D. 537) regulated the expense of funerals in Constantinople. The constitution refers to prior legislation of Constantine and Anastasius. The object of the regulation is well expressed in the following words:—It was to "secure men against the double calamity of losing their friends, and at the same time incurring heavy pecuniary liabilities on their account." Provision was made for securing interment to each person free of cost, and for protecting the surviving friends from the extortion of those who buried the dead. Funds were appropriated for the purpose of interment, which was conducted by persons appointed for the purpose, and with decency, but at little cost. All persons were to be buried alike, with some small allowance in favour of those who wished for a little more display at their own cost; but even this additional expense was limited; and it is said, "thus there will be nothing undetermined; but both those who wish to have funerals on a moderate scale will enjoy the advantages of our rule, and those who wish for more liberal arrangements will not be mulcted heavily, and will be enabled to show their liberality at moderate cost." The whole constitution is very curious; but a full explanation of it would require some labour. The objects of it have, however, been sufficiently stated here. The means by which they were accomplished would not be suitable to this country. ('Novell,' 59.)

At Bombay, says Niebuhr ('Reisebeschreibung,' &c. ii. 50), "the Parsees have a peculiar manner of interring their dead. They do not choose to rot in the earth like the Jews, Christians, and Mohammedans, nor be burnt like the Indians; but they let their dead be digested in the stomachs of birds of prey. They have at Bombay a round tower on a mountain at some distance from the city, which is covered on the top with planks. Here they place their dead, and after the birds of prey have eaten the flesh, they collect the bones below in the tower, and the bones of the men and women in separate vessels." Herodotus (i. 140) says of the ancient Magi, that they never interred their dead till they were torn by birds or dogs. In Herbert's 'Travels' (ed. 1638, p. 54), there is a representation of one of these Parsee towers. Some nations have eaten the aged, and also killed and eaten those who were attacked by disease, and thus anticipated the trouble of interment. This revolting practice is established on sufficient evidence. (Herodotus, i. 216, iii. 99; 'London Geog. Journal,' ii. 199; BATTAS, in GEOG. DIV.) Dr. Leyden states that the Battas frequently eat their aged or infirm relatives, as an act of pious duty. The Battas are not a ferocious, but a quiet and timid people. Niebuhr says in a note to the extract given just above, "At Constantinople I heard, that in the southern part of Russia there is a people who think that they can show to their dead friends and relations no greater honour than to eat them. So different are the opinions of mankind."

These are, however, singular exceptions to the general practices of all nations. Among the Europeans, and those descendants of Europeans who have settled in parts beyond Europe, the interment of the dead in the earth is the universal practice. It was proposed, indeed, to revive the practice of burning during the French revolution, but the proposal was not adopted. It has also been the practice of all nations called civilised, and perhaps of most nations called barbarous, to treat the dead with decency, and to accompany the funeral ceremony with religious rites.

The places set apart for the burial of the dead are generally called cemeteries, which is a Greek term signifying "a place of rest or sleep," and was applied to common places of interment by the early Christians. Among the Greeks, cemeteries were perhaps always without the cities. Among the Romans, the tombs were generally placed by the sides of the public roads. It was an enactment of the Twelve Tables that a dead body was not to be buried or burnt within the city (Dircksen, 'Zwölf-Tafel Fragmente,' p. 657). The prohibition against burning in the city is supposed by Cicero to have been made to prevent risk from fire: the reason for interment not being allowed within the city is not stated. A regulation of the Twelve Tables appears to have limited expenses at funerals (Dircksen, p. 665); and a law to the same effect was passed in the time of the Dictator Sulla (Plutarch, 'Sulla,' c. 35).

The early Christians followed the custom of the Romans in burying outside of cities; but they afterwards transferred their burial-places to the vicinity of the churches and within towns, where they have continuedt o be generally situated up to the present time, the churchyard being the usual place of interment, though, when the church is surrounded by houses, it is by no means a fit situation; for the putrid exhalations arising during the decomposition of animal bodies are injurious to health, and capable of giving rise to, or at least of encouraging, the progress of various pestilential diseases, of which the most common in this country are low nervous or typhus fevers. In all grounds used for interment low wet places should be avoided, and care should be taken that bodies are not interred near wells or rivers from which people are supplied with water.

The subject of interment possesses considerable interest in a legal point of view, for it is often of great importance to determine how long a body has lain in the ground; and by observing the changes which naturally take place in bodies at different stages of decomposition, it is possible in some cases to determine whether certain marks are the result of decomposition, or the remains of injuries inflicted before death.

The subject of interment attracted much attention in England for many years, and a great amount of information was collected by a special inquiry, of which the report was published by Edwin Chadwick, Esq. The report contains, in addition to the evidence on the injurious effects of crowded burial places, much valuable information on the injury to health caused, particularly among the poor, by the delay in interments. Among the poor in some parts of London the average time that a body is kept is about a week, which sometimes arises from inability to raise money for the funeral expenses, as well as other causes; and where there is only a single apartment, the dead and the living occupy it together. The injurious consequences to health from the presence of a dead body, sometimes in a state of rapid decomposition, in a small ill-ventilated apartment, and particularly when death has been the consequence of malignant disease, cannot be disputed; and the moral effect on the living is demoralising. The expense of funerals is another head which is examined in this report, where it is well remarked that "the expense of interments, though it falls with the greatest severity on the poorest classes, acts as a most severe infliction on the middle classes of society." The cost of interment in London varies from 4*l.* for a labourer, to 1000*l.* for a gentleman; for persons of the condition of a gentleman it is stated that 150*l.* would be a low average. But these charges do not include anything except the undertaker's bill. The account of the details of an expensive funeral, "which is strictly the heraldic array of a baronial funeral, the two men who stand at the doors being supposed to be the two porters of the castle, with their staves in black," &c., is ludicrous enough; but the disposition to laugh is checked by considering the pecuniary embarrassment which this absurd display often entails on the survivors.

The recognition of the numerous evils attendant on the usual church and churchyard interments, led, in 1852, to the passing of the Act 15 & 16 Vict., cap. 85, "to amend the laws concerning the burial of the dead in the Metropolis;" and this was followed in the succeeding year by the Act 16 & 17 Vict., cap. 134, for extending the provisions of the Act of 1852 to places beyond the metropolis, in England and Wales. Many other Acts for extending the powers or for regulating minor details have followed.* In 1855 the 18 & 19 Vict., cap. 68, extended the measure to Scotland, and the 19 & 20 Vict., cap. 98 (in 1856), to Ireland.

By these Acts intra-mural interments are rapidly being discontinued. In all towns or poor-law unions burial boards are constituted, with powers to raise funds and provide cemeteries in proper places, to regulate fees, &c., and to keep the burial-places in good order. The secretary of state for the Home department has the power of prohibiting interments in any intra-mural burying-ground which he may deem injurious to the surrounding community, inspectors are appointed, and a system of extra-mural interment is extending itself throughout the United Kingdom. No large towns in England, and few small ones, are now without one or more cemeteries, selected with regard to convenience and their sanitary qualifications; and it is stated that much improvement has been already effected alike in the position and character of the sites selected for the interment of the dead, and in the mode and expense of conducting funerals.

INTERMITTENT. [FEVER.]

INTERNAL and EXTERNAL, geometrical terms applied to the angles made by the sides of a bounded figure. The angle made by two sides is an internal angle; that made by a side and a side produced is an external angle.

INTERNATIONAL LAW. This term was originally applied by Bentham to what was previously called the "law of nations," and it has been generally received as a more apt designation than that which it superseded. When the term "law of nations" was in use, that of "law of peace and war" was sometimes employed as a synonym, and as indicative of the boundaries of the subject. It was thus in its proper sense restricted to the disputes which governments might have with each other, and did not in general apply to questions between subjects of different states, arising out of the position of the states with regard to each other, or out of the divergences in the internal laws of the separate states. But under the more expressive designation, international law, the whole of these subjects, intimately connected with each other as they will be found to be, can be comprehended and examined, and thus several arbitrary distinctions and exclusions are saved. To show how these subjects are interwoven, the following instances are taken:—A port is put in a state of blockade; a vessel of war of a neutral power breaks the blockade: this is distinctly a question between nations, to be provided for by the law of peace and war, in as far as there are any consuetudinary rules on the subject, and the parties will submit to them. But suppose a merchant vessel belonging to a subject of a neutral power attempts an infringement of the blockade, and is seized: here there is no question between nations in the first place. The matter is adjudicated on in the country which has made the seizure, as absolutely and unconditionally as if it were a question of internal smuggling; and it will depend on the extent to which just rules guide the judicature of that country, and not on any question settled between conteuding powers, whether any respect will be paid to what the party can plead in his own favour, on the ground of the comity of nations, or otherwise. But there is a third class of cases most intimately linked with these latter, but which are completely independent of any treaties, declarations of war, or other acts by nations towards each other. They arise entirely out of the internal laws of the respective nations of the world, in as far as they differ from each other. The "conflict of laws" is a term very generally applied to this branch of international law, and the circumstances in which it comes into operation are when the judicial settlement of the question takes place in one country, but some of the circumstances of which cognisance had to be taken have occurred in some other country where the law applicable to the matter is different. One of the most common illustrations of this subject is,—a judicial inquiry in England whether a marriage has taken place in Scotland according to the law of that country; or, an inquiry in Scotland whether a marriage has taken place according to the law of England; in either of which cases there will generally be the further and nicer question, Which country's law ought to prevail as the criterion?

Thus the three leading departments of international law are—

1. The principles that should regulate the conduct of states to each other.

2. The principles that should regulate the rights and obligations of private parties, arising out of the conduct of states to each other.

3. The principles that should regulate the rights and obligations of private parties, when they are affected by the separate internal codes of distinct nations.

The first of these has been the principal subject of the well-known works of Grotius, Puffendorf, Vattel, and other publicists, who have derived from general principles of morality and justice a series of minute abstract rules for the conduct of nations towards each other, and subsidiarily for the conduct of their subjects in relation to international questions.

It is clear that thus in its large features, as a rule for the conduct of independent communities towards each other, the law of nations wants one essential feature of that which is entitled to the term law—a binding authority. Nations even the most powerful are not without checks in the fear of raising hostile combinations and otherwise; but there can be no uniformity in these checks; and in general when the interest is of overwhelming importance, and the nation powerful, it takes its own way. The importance of the questions which may be involved in the law of nations thus materially affects the question how far it is uniformly obeyed. In many minor questions,—such as the safety of the persons of ambassadors, and their exemption from responsibility to the laws of the country to which they are accredited, and in other matters of personal etiquette, a set of uniform rules has been established by the practice of all the civilised world, which are rarely infringed. But in the more important questions,—regarding what is a justifiable ground for declaring war? what territory a nation is entitled to the sovereignty of? what is a legitimate mode of conducting a war once commenced? &c.—the rules of the publicists are often precise enough; but the practice of nations has been far from regular, and has been, as every reader of history knows, influenced by the relative strength of the disputing parties more than by the justice of their cause. The later writers on this subject have from this circumstance directed their attention more to the means by which any system of international law can be enforced, than to minute and abstract statements of what may be theoretical justice, but has little chance of being enforced. They have found several circumstances which have an influence in the preservation of international justice, though of course no sanctions which can give it the uniformity and consistency of internal laws.

The combinations for the preservation of what is called the Balance of Power [BALANCE OF POWER] are among the most useful restrictions of ambition. All periods of history furnish illustrations of this principle. Hume found that the Peloponnesian war was carried on for the preservation of the balance of power against Athens. The war with the French Republic and Empire exhibited a noted illustration of combination to prevent universal conquest on the part of the

---

* These have been collected, with notes and explanatory remarks, under the title of 'Burial Acts, Metropolitan and Provincial,' &c., by J. J. Scott, Esq. (Knight & Co., Fleet Street).

French. The late war with Russia exhibited a similar attempt to prevent the aggrandisement of Russia at the expense of Turkey. The safety of small states from being absorbed by their larger neighbours thus lies in the jealousy which their neighbours feel of each other's aggrandisement. So the jealousy of rulers is one barrier to national injustice. Another is public opinion: sometimes that of the nation whose rulers would be prepared to commit injustice—sometimes that of other nations. Of course it can only be to a very limited extent that the public feeling of a despotic government can check the grasping spirit of its rulers; but the public feeling of the constitutional and democratic states is the great check on the injustice that might be perpetrated by a nation when it becomes so powerful as Great Britain.

The seizure of the Danish fleet by the English during the war with Napoleon has been a subject of warm censure. Necessity—even the plea that Napoleon would have used the fleet to invade our own shores—has not been accepted in palliation of the act; and the manner in which it has been canvassed is very likely to prevent any government from adopting the precedent. The partition of Poland is an instance of national injustice condemned by the public feeling of countries other than those by which it was perpetrated; and it may be questioned whether the states which accomplished the partition may not yet suffer by it. Good fame in the community of nations is like respectability in private circles, a source of power through external support; and the conduct of Russia towards Poland has frequently diverted from the former the sympathy of free nations. It need scarcely be observed that the press, whether fugitive or permanent, is the most powerful organ of this public opinion, and that the views of able historians, jurists, and moralists, have much influence in the preservation of international justice.

Among the principal subjects of dispute in this department of international law are—the sovereignty of territory and the proper boundaries of states; questions as to discovery and first occupancy of barbarous countries; questions as to any exclusive right to frequent certain seas,—and here there is a well-known distinction between the broad ocean and the narrow seas that lie close to particular territories; questions regarding the right of navigation in rivers which may be either between the upper and lower territories, or between states on opposite banks; questions as to the right of harbour or fishing, &c.; and questions as to the right of trading with particular states. A very advantageous method of adjusting minor international disputes has been frequently had recourse to of late in a submission to the arbitration of a neutral power. Pride and the spirit of not yielding to intimidation or aggrandisement have often more influence in the resistance offered by one state to the claim of another, than the desire to keep what is demanded. In such a case the national pride is not injured when that which is yielded to is the award of a neutral party, not the demand of an opponent. It has been suggested by Bentham and Mill that the civilised states of the world should establish among themselves a congress, which should adjudicate on all disputes between its members, the members being excluded from voting in their own disputes.

The Second department into which international law is divided—the rights and obligations of individuals as affected by the conduct of states towards each other—has, like the first, been examined by the publicists in their theoretical manner; but it has never, perhaps, received so much practical illustration as it did in the British courts, particularly the Prize Court, during the war with France. In a despotic country it would of course scarcely ever occur that the bench should fail to give effect to the national policy of the government, whatever that may be. But in England it was the rule that foreigners as well as natives were entitled to the rigid administration of the law, and that, if the proceedings of the government were at variance with the rights of parties according to the law of peace and war, individuals might have redress. Thus, when Great Britain, in opposition to the Berlin decrees, tried to establish a "paper blockade," that is to say, by force of orders in council to declare places to be under blockade, whether there were a force present to support it or not, Sir William Scott found that "in the very notion of a complete blockade, it is included that the besieging force can apply its power to every point in the blockaded state. If it cannot, it is no blockade of that quarter where its power cannot be brought to bear."

It has frequently been observed, that as to all departments of the law of nations, uncivilised countries are at the mercy of the civilised: that not having any means of reciprocating the action of international laws, from their having no systematic judicatories of their own, they have not even the frail tenure of generally received opinions as to what the conduct of independent nations towards each other ought to be, for their protection. This is in some measure true. If a weak civilised nation, which can eloquently appeal to the law of nations, is feebly protected against the injustice of a strong nation, still less effectually is a barbarous community, which never heard of international law, and knows not how to appeal to its acknowledged principles, protected by it; and, in regard to such communities, the humanity and conscience of the powerful nations coming in contact with them are their protection, rather than any rules of international law. Thus when, as in the instance of a colonial government or otherwise, such a nation as the British has to deal with the inhabitants of a barbarous country, it cannot be said that these inhabitants have the law of nations to appeal to if they are unjustly treated, and there is no security for their being well and humanely used but the morality and conscience of the British nation and its government. How far civilised nations had in former times disregarded all feelings of common humanity in their intercourse with inferior races, the history of colonisation, and especially that relating to the continent of America, is a horrible record. In later days higher notions have been entertained of the responsibility of superior power, and the civilised man has in some measure ceased to make his first advances to the notice of the barbarian in the character of a murderer and a pillager. England has in this improved morality so far advanced before other nations, as to be the protector of barbarous races from the oppression of others, in her efforts for the abolition of the slave trade and the preservation of aboriginal nations. These efforts, in so far as they are an anomaly in the general conduct of nations, have introduced some necessary exceptions to the rules of international law applicable to the rights of persons. This has consisted in the necessity of treating those who are injured by the slave trade, namely, the slaves carried off, as if they were subjects of this country subjected to injury, while the deporters have likewise been of necessity treated in the general case as if they were subjects of this country doing the injury. The effect of this state of matters, as an exceptional principle in international law, sometimes occasions difficult questions. In one case a foreign slaver had been captured and taken possession of. The crew rose, and putting the captors to death, recaptured the vessel. They were tried and condemned to death for murder in an English court; the judge refusing to admit the plea that, as the capture had taken place under our laws, not their laws, they were entitled to regain possession by any means which they chose to adopt. He held it right, in fact, to treat the ship as a prison, and the captured seamen as persons in a British prison. On the question, however, coming before the judges, the conviction was quashed, the ground of reversal being, that the vessel not having slaves on board was not liable to seizure. In those cases where it is necessary to diverge from the general principle of international law, for the protection of the weak, it is fortunate that the humane and enlightened motive of proceeding is a guarantee for its being beneficially exercised.

The rights of individuals have sometimes been so much affected by the conduct of nations towards each other, that their own nation has been induced to make war against the nation aggressing. This has twice occurred in our intercourse with America: one war was caused by our restrictions on the commerce of America by the orders in council; another by our searching American merchant vessels for British seamen. This subject of "the right of search," as it is termed, is still in an unsatisfactory and unsettled state.

The Third division of international law is that which most properly comes under the head "Conflict of Laws," namely, the principles that ought to regulate the rights and obligations of private parties when they are affected by the separate internal codes of distinct nations. This involves questions with individuals, and not, at least in the first instance, questions with states; and the adjustment of each question depends on the view taken by the law of the country to which the individual or his property is amenable. But it has this distinctive feature, that the circumstances under which disputes arise are not in the conduct of one nation towards another, but in differences between the internal laws of the countries, which internal laws disagree, not because the one nation has a dispute with the other, but in the general case because its legislators have taken its internal situation solely into consideration, and have overlooked the existence of other nations. There can be no part of the world where this species of international law can be so well illustrated as in the United States—a collection of communities, each having an internal system of administration, but each acting on principles of harmony and alliance with the other states of the Union. It is thus natural that America should have produced the best work on the subject, in Professor Story's 'Commentaries on the Conflict of Laws Foreign and Domestic, in regard to Contracts, Rights, and Remedies; and especially in regard to Marriages, Divorces, Wills, Successions, and Judgments,' of which two editions are now known and esteemed in this country. The leading rule of international law in this department is, that each civilised nation is to give efficacy to the laws of another country, unless its own laws or the general principles of justice are thereby invaded. We have the broadest and most distinct illustrations of this rule in the criminal law. The progress of opinion has lately been in favour of each nation rendering back fugitive criminals, to be dealt with according to the law of the country where they have committed any private crime against person or property. In conformity with this principle, treaties have been made with several states, for enforcing which, in this country, acts of parliament have been passed enabling the secretary of state, on the requisition of the ambassador or other representative, to issue a warrant to magistrates to seize a person accused of a crime, a magistrate being enjoined to put it in force on his being satisfied that the charge is of such a nature as would authorise him to commit a person charged with perpetrating it in his own jurisdiction. [Convention Treaties.]

But it has been a rule in many countries, and particularly in our own, that no aid is to be given for the enforcement of the political laws of foreign states. And hence as in other branches of international law, our enlightened principles on the subject of slavery have here been the cause of perplexing difficulties. With slave-holding countries slavery comes to be a question of property, but with us it can only be a question of government; and we cannot view any rules regarding property in slaves as laws relating to private rights, an infringement of which, when held to be criminal in the slave-holding country, must be so also here. Accordingly in the celebrated case of the Creole, in 1841, when certain American slaves escaped and found protection in a British settlement, it was found that we could not send them back to their owners as robbers who had with violence stolen their own persons from the custody of their proprietors.

As on the one hand the criminal law is that to which this department of international law most broadly and distinctly applies, on the other hand the position of real or landed property is that to which it has generally the least reference. The reasons of this distinction are obvious: his own personal conduct is that object of the law which a man most completely carries about from one country to another; his connection with landed property is the relation in which a tribunal out of the country in which the property is, can have the least chance of adjudicating. Between these extremes there are many questions regarding persons in their relations to each other, and regarding contracts as to moveable or personal property. It came thus to be a general principle, that rights connected with landed property must always be settled by the law of the place where the land lies, while questions regarding other property might be subjected to other criterions of jurisdiction. Perhaps historical circumstances in the early history of the European nations favoured this division. The various tribes which occupied the territory of the Roman empire appear to have carried with them their own peculiar laws and customs. (Savigny quotes a letter from Bishop Agobardus, in which he says it often happens that five men, each under a different law, may be found walking or sitting together—a state of society at this day exemplified in some oriental nations.) Among all these distinct tribes the feudal system arose as the general and uniform territorial law; while by reason of circumstances which need not be here narrated, the civil law became the ruling principle as to persons in their relation to each other when that relation was not of a feudal character, and as to claims regarding moveable goods. The common law of England has, from other circumstances, the least affinity with the other European codes in respect to personal relations. But it has fortunately happened that those departments of the law with which international questions are chiefly concerned,—the consistorial and the admiralty law, have been considered as the legitimate offspring of the civil law, and have adopted in a great measure its principles as they have been in practice throughout Europe. The mercantile law of England again has accommodated itself to the custom of merchants; this custom arising, in a great degree, out of the adaptation to modern commerce of the principles of the civil law (the portion of it least in harmony with that of other countries being the bankruptcy law, which is entirely statutory), has consequently adapted itself to the exigencies of foreign commerce.

The conflicts of laws between England and Scotland are to us of course the most important and interesting. The consuetudinary law of England has perhaps fewer principles in common with that of Scotland than the latter has with the law of any other country in Europe; and this divergence has been the cause of many difficult questions. In these the law of marriage and that of succession have been particularly fertile. In the former the difference between the institutions of the two countries, when subjected to the principles of international law, has been productive of very remarkable effects. On the subject of succession fortunately a series of decisions in both countries has settled two very important principles—that in the case of landed property it follows the *lex rei sitæ*, or the law of the place where the property is; while in moveable or personal property it follows the *lex domicilii*, or law of the domicile in which the person leaving it died.

INTERPLEADER, the name of an action at law, and of a proceeding in equity. When a person holding goods, or owing a debt or duty, is sued by two or more claimants, the court will order them to interplead upon the application of the party sued, and upon his delivering up or offering to deliver up the matter in dispute, and disclaiming all interest therein. The Sheriff when goods seized by him are claimed by some other person than the execution debtor, may also interplead, to have the right ascertained. A similar process is in use in the County Courts.

INTERPOLATION. Every mathematical table consists of a series of values of some algebraical expression corresponding to equidistant values of the letter on which it depends. Thus, the most extensive table of logarithms in common use is a succession of values of log. x, answering to $x = 10{,}000$, $x = 10{,}001$, $x = 10{,}002$, and so on up to $x = 99{,}999$. The process of interpolation is that of inserting in a table values of the tabulated function intermediate to those given in the table. For example, suppose that p, q, r, s, &c., are written in a table opposite to a, $a + b$, $a + 2b$, $a + 3b$, &c., and it is demanded what is the value of the function corresponding to $a + 2\frac{1}{2}b$: this is a question of interpolation.

Such a question can only be solved approximately, but, generally speaking, the values in the table are themselves but approximations, and the interpolated values are as correct as the tabular ones. Strictly speaking, the question itself is indeterminate, for no function can be determined by means of any finite number of values, however great. The question is precisely analogous to that of drawing a curve through a given number of points, which may be done in an infinite number of ways, how many points soever there may be. But if the points be gradually increasing in distance from a given line, and if it be a condition that the intermediate points must do the same, then if the points be near together, any two curves which satisfy the conditions must very nearly coincide. If equidistant abscissæ of such a curve be tabulated with their ordinates, then the ordinates corresponding to intermediate abscissæ will be very nearly the same for any curve which can pass through the points which belong to the tabulated ordinates.

The method of interpolation consists entirely in the application of the following theorem. [DIFFERENCE.] Let p, q, r, s, t, &c., be terms of a series corresponding to a, $a + b$, $a + 2b$, &c., and let the successive differences be formed, as in the following table:

$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$
a	p			
		Δp		
$a+b$	q		$\Delta^2 p$	
		Δq		$\Delta^3 p$
$a+2b$	r		$\Delta^2 q$	
		Δr		$\Delta^3 q$
$a+3b$	s		$\Delta^2 r$	
		Δs		$\vdots$
$a+4b$	t		$\vdots$	
$\vdots$	$\vdots$	$\vdots$		

where Δp is $q-p$, &c., $\Delta^2 p$ is $\Delta q - \Delta p$, &c. Then the nth term reckoned from p exclusive is

$$p + n\,\Delta p + n\,\frac{n-1}{2}\,\Delta^2 p + n\,\frac{n-1}{2}\,\frac{n-2}{3}\,\Delta^3 p + \text{\&c.} \quad \text{(A).}$$

Thus q is $p + \Delta p$, r is $p + 2\Delta p + \Delta^2 p$, and so on. This series, which gives the rest of the table accurately, will give the intermediate values approximately, if p, Δp, $\Delta^2 p$, &c., diminish rapidly. Thus, by making $n = \frac{1}{2}$, we find the term which should stand opposite to $a + \frac{1}{2}b$, if the table were made twice as minute as it now is, or, as we may say, *bisected*: if $n = 2\frac{1}{2}$, we find the term answering to $a + 2\frac{1}{2}b$, and so on. The following is an instance:—

Given the present value of 1,000,000*l.* 20 years hence, at 2, 4, 6, 8, and 10 per cent.: to deduce from thence an approximation at the rate of $4\frac{1}{2}$ per cent. Let it be observed, that from 2 to $4\frac{1}{2}$ is one interval and a quarter of the tables, or $n = 1\frac{1}{4}$.

2	672971				
		− 216584			
4	456387		+ 72002		
		− 144582		− 24677	
6	311805		+ 47325		+ 8705
		− 97257		− 15972	
8	214548		+ 31353		
		− 65904			
10	148644				

We have taken this example to show, when the intervals of the tables are considerable, how slowly the differences may diminish. The consequence is that only four places of the result will be correct. We have now

$$p = 672971 \qquad \Delta^3 p = -\,24677$$
$$\Delta p = -\,216584 \qquad \Delta^4 p = +\,8705$$
$$\Delta^2 p = +\,72002$$

$$n = \frac{5}{4},\quad \frac{n-1}{2} = \frac{1}{8},\quad \frac{n-2}{3} = -\,\frac{1}{4},\quad \frac{n-3}{4} = -\,\frac{7}{16},$$

$$n\,\frac{n-1}{2} = \frac{5}{32},\quad n\,\frac{n-1}{2}\,\frac{n-2}{3} = -\,\frac{5}{128},$$

$$n\,\frac{n-1}{2}\,\frac{n-2}{3}\,\frac{n-3}{4} = \frac{35}{2048}.$$

$$\begin{array}{rrr}
 & & 672971 \\
\frac{5}{4} \times & -216584 = & -270730 \\
\frac{5}{32} \times & 72002 = & +\;\;11250 \\
-\frac{5}{128} \times & -\;24677 = & +\;\;\;\;964 \\
\frac{35}{2048} \times & 8705 = & +\;\;\;\;149 \\
\hline
 & \text{Answer} & 414604 \\
 & \text{Correct Answer} & 414643
\end{array}$$

The smaller the tabular interval, the more correctly will a given number of differences serve to make the interpolation. Let us take the preceding question on the supposition that the rates are 2, 3, 4, 5, and 6 per cent., in which from 2 to $4\frac{1}{2}$ is $2\frac{1}{2}$ intervals, or $n=2\frac{1}{2}$.

$$\begin{array}{c|lllll}
2 & 672971 & & & & \\
 & & -119295 & & & \\
3 & 553676 & & +22006 & & \\
 & & -97289 & & -4215 & \\
4 & 456387 & & +17791 & & +838 \\
 & & -79498 & & -3377 & \\
5 & 376889 & & +14414 & & \\
 & & -65084 & & & \\
6 & 311805 & & & &
\end{array}$$

$$n=\frac{5}{2},\ n\,\frac{n-1}{2}=\frac{15}{8},\ n\,\frac{n-1}{2}\,\frac{n-2}{3}=\frac{5}{16},$$

$$n\,\frac{n-1}{1}\,\frac{n-2}{3}\,\frac{n-3}{4}=-\frac{5}{128}.$$

$$\begin{array}{rrrr}
 & & & 672971 \\
\frac{5}{2} & \times -119295 & = & -298238 \\
\frac{15}{8} & \times +22006 & = & +41261 \\
\frac{5}{16} & \times -4215 & = & -1317 \\
-\frac{5}{128} & \times +838 & = & -33 \\
\hline
 & & \text{Answer} & 414644 \\
 & & \text{Correct Answer} & 414643
\end{array}$$

The most simple interpolation is that which takes first differences only into account, and is perfectly well known to every one who can use a table of logarithms, or interpose arithmetical means.

We now give some instances in which the intermediate terms are expressed by means, not of the differences of given terms, but of the terms themselves. The case which most often occurs is that in which it is required to bisect the interval of the tables, and in this case a rule may be given which amounts to using the *third* differences, and is extremely simple. Let p, q, r, and s be successive terms of a table, and let it be required to find the term intermediate between q and r, that is, if q and r stand opposite to x and $x+y$, required the term answering to $x+\frac{1}{2}y$. The following formula shows the process :—

$$\frac{q+r}{2}+\frac{(q+r)-(p+s)}{16}\ \ldots\ (\text{B}).$$

Thus in the preceding instance—

$$\begin{array}{rr}
p=553676 & q+r=833276 \\
q=456387 & p+s=865481 \\
r=376889 & 4)-32205 \\
s=311805 & 4)-8051 \\
 & -2013 \\
 & \frac{1}{2}(q+r)=416638 \\
 & \text{Answer}\ \ 414625
\end{array}$$

This more simple rule is equivalent to the use of the preceding method with p and its first three differences. It requires that two terms should lie on each side of the term sought; but if it were required to bisect the interval between p and q by means of p, q, r, and s, the formula is as follows :—

$$q-\frac{5(r-p)-(s-q)}{16}\ \ldots\ (\text{C})$$

Thus, to find the value at $3\frac{1}{2}$ per cent. from the preceding data, we have—

$$\begin{array}{rr}
r-p= & -176787 \\
 & 5 \\
\hline
 & -883935 \\
s-q= & -144582 \\
\hline
5(r-p)-(s-q)= & 4)-739353 \\
 & 4)-184838 \\
 & -46210 \\
q= & 456387 \\
\hline
\text{Answer} & 502597 \\
\text{Correct Answer} & 502566
\end{array}$$

The formula for the bisection of the interval of r and s by means of p, q, r, and s, is—

$$r+\frac{5(s-q)-(r-p)}{16}\ \ldots.\ (\text{D}).$$

Where extreme accuracy of bisection is required, the following rule will be equivalent to going as far as fifth differences, and taking from the table three terms on each side of the intermediate term required.

Let the terms of the table be p, q, r, s, t, and u, the intermediate term of r and s being required.

$$\begin{array}{ccc}
p & q & r \\
u & t & s \\
\hline
u+p=x & t+q=y & s+r=z
\end{array}$$

$$\text{Intermed. term}+\frac{z}{2}+\frac{25(z-y)+3(x-z)}{256}\ \ldots.\ (\text{E}).$$

As an instance, take from the article Interest the logarithms to ten places of 1·01, 1·02, 1·03, 1·04, 1·05, and 1·06, for p, q, r, s, t, and u, neglecting decimal points and preliminary ciphers.

$$\begin{array}{rrr}
43213738 & 86001718 & 128372247 \\
253058653 & 211892991 & 170333393 \\
\hline
x=296272391 & y=297894709 & z=298705640 \\
298705640 & & 297894709 \\
\hline
-2433249=x-z & & z-y=\ 4)81093100 \\
3 & & 20273275 \\
\hline
-7299747 & & -7299747 \\
 & & 8)12973528 \\
\frac{1}{2}z=\ 149352820 & & 8)\ 1621691 \\
50678 & & 4)\ 202711{\cdot}4 \\
\text{Ans.}\ \ {\cdot}0149403498=\text{log. }1{\cdot}035 & & 50677{\cdot}9
\end{array}$$

The formula (B) is sufficient to bisect the intervals given in the article cited.

The following is the method by which the formula (A) may be expressed in terms, not of p, $\triangle p$, &c., but of p, q, r, &c. Suppose this is to be done as far as the third difference, or in terms of p, q, r, and s. Assume for the function in question

$$\text{A}\,(n-1)(n-2)(n-3)+\text{B}\,n(n-2)(n-3)+\text{C}\,n(n-1)(n-3)+\text{D}\,n(n-1)(n-2).$$

When $n=0$, this should be p; but it then becomes $-6\,\text{A}$, whence $\text{A}=-\frac{1}{6}p$. When $n=1$, this should be q; but it then becomes $2\,\text{B}$, whence $\text{B}=\frac{1}{2}q$. Similarly $\text{C}=-\frac{1}{2}r$, and $\text{D}=\frac{1}{6}s$: or the function tabulated, within the given limit, is, so far as third differences can determine it,

$$n(n-1)\left\{\frac{n-2}{6}s-\frac{n-3}{2}r\right\}$$

$$+(n-2)(n-3)\left\{\frac{n}{2}q-\frac{n-1}{6}p\right\}$$

This method may be extended to the interpolation of intermediate values, when the given values are not equally distant. Suppose that according as n is a, b, or c, a function is p, q, or r. Assume for the function

$$\text{A}\,(n-b)(n-c)+\text{B}\,(n-a)(n-c)+\text{C}\,(n-a)(n-b).$$

Then when $n=a$, we must have $\text{A}\,(a-b)(a-c)=p$, or

$$\text{A}=\frac{p}{(a-b)(a-c)};\ \text{B}=\frac{q}{(b-a)(b-c)};\ \text{C}=\frac{r}{(c-a)(c-b)}.$$

The following results will serve as an instance of the application of the last method but one. Suppose it required to interpose four equidistant values between q and r in the series p, q, r, s, using third differences inclusive. First interpose four arithmetical means between q and r, and let them be A, B, C, D: then interpose four arithmetical means between $3q-2p-s$, and $3r-2s-p$, and let these be A′, B′, C′, and D′. Then the four terms intermediate between q and r must be

$$\text{A}+\tfrac{8}{300}\text{A}',\ \text{B}+\tfrac{4}{100}\text{B}',\ \text{C}+\tfrac{4}{100}\text{C}',\ \text{D}+\tfrac{8}{300}\text{C}'.$$

If it be required to interpose three equidistant values between q and r, using third differences, take p, q, r, s, and between q and r interpose three arithmetical means, A, B, and C; also between $3q-2p-s$ and $3r-2s-p$ interpose three means, A′, B′, and C′. Then the three terms required are

$$\text{A}+\tfrac{1}{32}\text{A}',\ \text{B}+\tfrac{1}{24}\text{B}',\ \text{C}+\tfrac{1}{32}\text{C}'.$$

To interpose two terms, still with third differences, find two arithmetical means between $30q-2p-s$ and $30r-2s-p$; the twenty-seventh parts of these means are the intermediate terms required. The interpolation of one term has already been given (B).

When second differences only are used, no material simplification of the fundamental rule can be given. To place k intermediate terms between q and r by means of q, r, and s, interpose k arithmetical means, and correct them as follows. Calculate $(q+s-2r)\div 2(k+1)^2$, and call this A; then subtract from the several means

$$k\,\text{A},\ 2(k-1)\,\text{A},\ 3(k-2)\,\text{A},\ \ldots\ (k-1)\,2\,\text{A},\ k\,\text{A}.$$

It would be a little more correct to let A be $(p+r-q-s)\div 4(k+1)^2$, which in the case of a single intermediate term would amount to using third differences.

INTERPRETATION. (Mathematics.) This word is coming into use as descriptive of a process which it has long been customary to employ, though without any express name. When an algebraical definition is laid down, there is frequently some restriction implied in the manner of making the definition, so that the process to which it leads presents more cases than can be explained by it, or were contemplated when it was made. For example, the abbreviation of a, aa, aaa, &c. [Exponent] into a, a^2, a^3, and the rules which spring from it, soon lead to such results as—

$$a^{-3}, \quad a^{0}, \quad a^{\frac{1}{2}}, \quad a^{-\frac{1}{2}};$$

which, though they follow from algebraical processes, yet when they first arrive, are without algebraical meaning. In such a case, the process of interpretation enters; the question is, What should such symbols mean? have they a necessary meaning? if not, is there any meaning which will be more convenient than another? A definition has been laid down, leading to results which cannot be explained by it: required the extension of the definition which will enable it to explain its own results.

Examples are found in all works which explain the principles of algebra. The rule always is, let the interpreted meaning of the new symbols be such as will make the whole of the process true by which they were obtained. Now as they must have been obtained by the application of those formulæ which are true of the intelligible results of the definition, the rule just mentioned leads to the following: let the meaning of the unintelligible results be such as will make the formulæ of the intelligible ones true of them. Thus, in the preceding instance, the fundamental formula which connects the terms of the series a, a^2, a^3, a^4, &c., is—

$$a^{m} \times a^{n} = a^{m+n}$$

which is intelligible when m and n are positive whole numbers, Suppose it now required to interpret a^{0}: that is, to give it a meaning which shall make the preceding formula true of it. Write 0 instead of m and we have $a^{0} \times a^{n} = a^{0+n} = a^{n}$, or a^{0} must stand for 1. Again, suppose it required to interpret $a^{\frac{1}{2}}$. In order that the preceding formula may be true of the meaning of $a^{\frac{1}{2}}$, we must have

$$a^{\frac{1}{2}} \times a^{\frac{1}{2}} = a^{\frac{1}{2}+\frac{1}{2}} = a^{1} \text{ or } a$$

whence $a^{\frac{1}{2}}$ must stand for $\sqrt{a}$. And similarly for other cases.

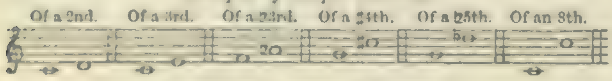
It is interpretation which creates the distinction between algebra, as now known, and arithmetic with general symbols of number, or universal arithmetic. This we shall see in the article Negative and Impossible Quantities.

INTERROGATORIES. [Equity.]

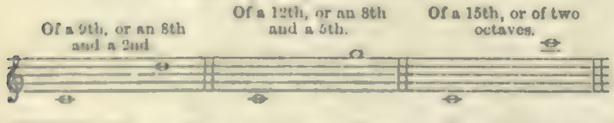
INTERVAL, in Music, is described by Dr. Robert Smith, in his 'Harmonics,' as "a quantity of a certain kind, terminated by a graver and an acuter sound." Brossard has said the same thing in other words:—"C'est la différence, ou distance, qu'il y a d'un son grave à un son aigu." Agreeing in this definition, from C to D is an interval of a 2nd; from C to G an interval of a 5th; from C to B♭ an interval of a flat 7th, &c. [Scale.]

Intervals are *simple* when confined within the octave, *compound* when they exceed it, and are named according to the distance of the two boundary notes. Thus the interval of a whole tone (C D) is called a 2nd; of a whole tone and a semitone (C E♭), a minor 3rd, &c. Intervals, therefore, are considered as sounds, and hence are either consonant or dissonant; that is, concords or discords. [Concord; Discord.]

Examples of Simple Intervals.



Examples of Compound Intervals.



Of a 9th, or an 8th and a 2nd
Of a 12th, or an 8th and a 5th.
Of a 15th, or of two octaves.

INTESTACY is either the dying without a will, or leaving a will which does not dispose of the whole of the real or personal estate. There may therefore be either a general or a partial intestacy.

INTONATION, in Vocal Music, is the tuning of the voice—the singing true or false—in tune or out of tune. Correct *intonation* is the first requisite in a singer; this wanting, all his other musical qualities, however good, are unavailing.

INTRADOS and EXTRADOS, the lower and higher curves of an arch. The intrados of an arch is also called the *soffit*. The intrados and extrados are measured respectively along the inside and outside of the voussoirs. [Arch.]

INTUITION (*intueri*), the most simple act of the reason or intellect, on which, according to Locke, "depends all the certainty and evidence of all our knowledge; which certainty every one finds to be so great, that he cannot imagine, and therefore cannot require, a greater. For a man cannot conceive of a greater certainty than that any idea in his mind is such as he perceives it to be, and that two ideas, wherein he perceives a difference, are different and not precisely the same." His definition, or rather explanation, of intuition is as follows:—"Sometimes the mind perceives the agreement or disagreement of two ideas immediately by themselves, and this, I think, we may call intuitive knowledge. In this the mind is at no pains of proving or examining, but perceives the truth as the eye does the light, only by being directed to it." ('Essay on Human Understanding,' b. iv., c. ii., § 1.) Sir W. Hamilton ('Lectures on Metaphysics,' lect. xxiii.) observes that "an intuitive cognition, as an act, is complete and absolute, as irrespective of aught beyond the dominion of consciousness; whereas a representative cognition, as an act, is incomplete, being relative to and vicarious of an existence beyond the sphere of actual knowledge."

The nature of the relation which subsists between intuition and reasoning has been strongly contested. While Beattie maintains that the connection between them, how closely soever they are found in general to be connected, is not necessary, but, on the contrary, a being endued with one may be destitute of the other; Dugald Stewart, on the other hand, insists that the two are not radically distinct, although by most writers they are considered to be different faculties. Locke having rightly maintained that every step which the reason makes in demonstrative knowledge has intuitive certainty, and that, consequently, the power of reasoning presupposes that of intuition, Stewart thinks that the intuition of Locke implies the power of reasoning; or, at least, that intuition combined with memory explains reasoning. Here his usual sagacity appears to have failed Stewart. While the mind itself is perfectly simple, it has been, for the purpose of attaining accuracy of language and distinctness of theory, supposed to be multiple; and distinct faculties have been ascribed to it according as its several operations comprise more or fewer elements. According, therefore, to his own account, reason, which involves the element of time, must be kept distinct from intuition, which does not involve that element.

The proper objects of intuitive certainty are identical propositions. This, of course, does not mean propositions verbally identical; such as "a man is a man." But while the object of thought is perfectly and always one, it may present itself to the thought under a variety of aspects, either dissolved into its elements or as combined into a whole. It is this identity under an apparent diversity that constitutes that original and primary evidence which makes certain propositions, as soon as the respective terms are understood, to be perceived intuitively. On the other hand, the apparent identity of a real diversity is the ground of all sophistical argument. The ultimate form of legitimate argumentation is, $a = b$, $b = c$, $\therefore a = c$. But every fallacy, when detected, will invariably be found to be $a = b \pm r$, $b = c$, $\therefore a = c$. The sophistry consists in the suppression of the element r, either positive or negative.

INULA HELENIUM (Elecampane), an indigenous perennial herbaceous plant, found in most meadows, the root of which is used in medicine. This part is thick and branching, brown externally, white internally, with an aromatic odour and a mucilaginous taste, at first bitter, afterwards sharp and camphor-like. In addition to mucilage it contains a large quantity of a variety of starch termed *inulin*. Inulin exists in many other plants, and goes by a variety of names,—Alantin, Menzanthin, Elecampanin, Dahlin, Datiscin. *Inula helenium* also contains a volatile oil, a portion of which when crystallised constitutes the stearopten called Elecampane camphor; a bitter extractive; an acrid resin; some salts of lime, &c.

These ingredients give it a tonic and stimulating property, and it is employed in debility of the stomach and other diseases of mucous surfaces unattended with inflammation. It is, however, not much used. Having kept its place in popular favour from the time of the earliest Greek writers, it cannot be deemed altogether useless. It affords a ready substitute for senega, the virtues of which are greatly lessened by age, and can rarely be had fresh. The *Inula conyza*, formerly *Conyza squarrosa*, a plant not uncommon by the sides of fields or roads in chalky districts, is deservedly esteemed in the east of Europe as an antidote against the bites of vipers. It is remarkable that such an antidote has, in different parts of the world, been supposed to be found in the tribe of *Compositæ*, such as *Mikania guaco*, *Eupatorium agapana*, *Inula viscosa*, *Prenanthes serpentaria*, *Vernonia altissima*, &c.

INULIN, *Dahlin*, *Alantin*, *Menzanthin*, *Datiscin* ($C_{12}H_{10}O_{10}$?), a neutral vegetable principle, resembling starch in many of its properties; it exists in the root of elecampane (*Inula helenium*), the *Helianthus tuberosus*, the *dahlia*, and some other plants. The roots are reduced to a pulp, which is to be placed on a very fine sieve, and a stream of water is to be poured upon it as long as the latter is rendered milky; the inulin is then allowed to deposit; the supernatant liquor being poured off, the deposit is to be repeatedly washed with water till it comes off perfectly limpid.

Inulin when dry has the following properties:—It is a white brittle mass composed of crystalline grains, or else a fine and white powder, which adheres to the teeth. It is insipid, insoluble in cold water, but very soluble in boiling water; the solution is fluid, and not gelatinous like that of starch. When it is very dilute, it does not become turbid on cooling; but alcohol, not being a solvent of inulin, precipitates it from this solution. When heated to above 212°, it melts, and is converted into a sweetish mass which is very soluble in cold water (*pyro-inulin*). Cold sulphuric or nitric acid converts it into the same substance.

Iodine renders inulin of a brown tint, which is fugitive. Lime-water, solution of tin, subacetate of lead, tincture of galls, protosalts of mercury, and salts of silver, do not precipitate the solution of inulin; the alkalies act upon it as they do on starch.]

Dilute boiling sulphuric acid converts inulin rapidly into glucose; this effect is also produced when inulin is heated alone: the glucose produced undergoes the spontaneous fermentation when mixed with yeast.

INVARIABLE (Mathematics), the same word in meaning as CONSTANT, which see. There are however two sorts of constants, which it is desirable to treat under different names: the first, which we may call a constant, or a common constant, meaning a quantity which is absolutely invariable; the second meaning a function which may vary, but which does not vary in the processes required by a given equation. This we propose to call the invariable function of that equation, or its invariable.

Thus, in a common differential equation, which is supposed to be true of y and x when x passes through all stages of magnitude whatsoever, the only invariable is an absolute invariable, or a common constant. But in an equation of differences, in which x only passes from one whole number to another, the invariable function is any one which remains unaltered by changing x from one whole number to another. Thus [INTEGRATION, FINITE], instead of saying that the solution of $\Delta y = x + 1$ is $y = \frac{1}{2}(x^2 + x) + \mathrm{C}$, where C is a constant, we may allow C to be any function of x, which is unaltered by changing x from one whole number to another. Such a function is $\phi(\cos. 2\pi x)$, so that the solution is $\frac{1}{2}(x^2+x)+\phi(\cos. 2\pi x)$, and the last term is the invariable of the equation.

Again, suppose it required to solve the functional equation $\phi(x^2) = 2\phi x$. One solution of this is $\phi x = c \log. x$, where c is any absolute constant. But the equation is solved if c be a function of x, provided it be one which does not change when x is changed into x^2. Such a function is

$$\cos. \left\{ 2\pi \frac{\log. \log. x}{\log. 2} \right\} \text{ or any function of it,}$$

$$\text{or } \phi x = \text{any function of } \cos. \left\{ 2\pi \frac{\log. \log x}{\log 2} \right\} \times \log x.$$

General methods of finding invariable functions, as far as they have yet been given, will be found in the 'Encyclopædia Metropolitana,' article 'Calculus of Functions.'

INVENTION (in the Fine Arts). This term, when used in the language of art, has a different signification from what it usually bears in common language. It does not mean *discovery*, but combines *conception*, or the peculiar way in which an artist's mind takes cognisance of a subject to be represented, with the *mode of treatment*, or choice of objects and manner of disposing them best adapted for producing a desired effect. Thus, in painting and sculpture, it is the faculty by which the most perfect mode of illustration, by form or by colour, is suggested to the artist, and by which the mind of the spectator is led to comprehend the truth, the intention, and the whole purpose of the work before him. But so distinct is it at the same time from perfect execution, that it is often found to exist independently of excellence in that particular, some of the finest inventions in art being manifestly defective in technical requirements.

It is hardly necessary to enter into the question whether the power of invention be a primary and original law of the mind, or whether the effect of cultivation. But admitting invention to be a gift of nature, and not reducible to rule, nor to be taught by any regular process, it still may be improved by study. Whatever natural disposition or original capacity may exist—and it will not, we suppose, be denied that some minds are more bountifully endowed than others—every power short of *creation* must have groundwork and foundation *on* which and *out of* which to exercise itself; and even the inventive faculty, which seems to approach nearest to creation, depends upon knowledge, by whatever means acquired, for materials with which to develope and declare itself.

Raffaelle, by the wonderful ability which he has shown in choosing subjects in which the greatest quantity of matter or incident could be introduced, and then in representing them at the most critical moment for illustration, in combining all the most striking and affecting circumstances, and filling the spectator's mind with the whole story, by bringing before him, as it were, the past, the present, and even suggesting that which is to follow, may justly be considered the greatest master in invention. He was gifted, if any man ever was, with the fullest portion of natural and inherent genius, but he attained his eminence by the most persevering course of exercise and observation, as the necessary and only means through which the inventive faculty could be manifested. He studied nature diligently and profoundly in all her varieties of beauty and expression. Nothing seems to have escaped him; everything that offered itself out of her great storehouse was treasured as serviceable to his art, and he acquired such an accumulation of materials, to serve as handmaids to his invention, that whatever subject came before him found him prepared, and was immediately dignified with all the expression, truth, propriety, and completeness, if we may use the word, that it was capable of receiving. Raffaelle never reached the perfect beauty and character almost superhuman which appear in the finest works of the Greeks, nor, in colour, the magic and brilliancy and breadth of Titian, another master-spirit; yet, in the largest and most comprehensive sense of the quality we have been describing, he stands (perhaps with one mighty exception) without an equal or a rival.

The examples which may be most satisfactorily adduced in illustration of invention in the fine arts, both for their excellence and for the facility of reference, as we are so fortunate as to possess them in this country, are the Cartoons of Raffaelle preserved at Hampton Court. Of these the 'Paul preaching at Athens,' 'The Sacrifice at Lystra,' and 'The Death of Ananias,' may be selected as the most remarkable for the quality we have been considering. [CARTOONS.]

Though in a totally different style, the frescoes of Michel Angelo, in the Sistine Chapel at Rome, may be equally quoted as triumphs of invention. The comprehensiveness of his scheme of illustration, and the greatness and energetic character of his design and composition, render this one of the finest monuments that art has to boast. In viewing the magnificent works of Michel Angelo in this chapel, and of Raffaelle in the loggie and stanze of the same palace (the Vatican), the spectator has a series of examples of as wonderful efforts of inventive genius in historical design as it seems possible to produce.

It should be observed here that invention is quite independent of the *class* of design; its force and power may be displayed in every part of the art, and in subjects of inferior grade, or even in the mode of treating colour, light, and shade. Rembrandt, to proceed with further illustration, is one of those who displayed very high powers of invention; "a genius," Fuseli truly says, "of the first class in whatever relates not to form;" and he justly eulogises his "powers of nature," and "the grandeur, pathos, and simplicity of his composition." Thus also, though the quality of his art was not of the highest class, the merit of invention is pre-eminently due to our own Hogarth. Turner, again, in a branch of art which by some is supposed to afford little scope for this faculty, has shown rare affluence of invention, based on close study of natural phenomena, and great imaginative and analytical power.

We have referred only to a very few out of the numerous artists whose works are worthy of attention as examples of invention; and have confined ourselves to some of the leading painters, though we might easily multiply them from productions in the sister art. Enough however has been said to point out the nature and value of that high quality in design, and to enable the intelligent observer to recognise and appreciate it when he meets it in the productions of artists, and discriminate between the efforts of elevated and original minds and the commonplace performances of mere mechanical imitators.

INVENTION and DISCOVERY. The rights of individuals, as to the honour due to the origination of new views, processes, or methods, are matters of constant discussion in the history of letters and science. It is strange that the subject should never have been generally treated: and in default of better, we intend to put together some rude materials for consideration, which may perhaps help the young reader of the history of science (from which our examples will mostly be drawn) in forming his opinion of the controversies which there abound.

Invention and discovery are, for our present purpose, synonymous terms: in older English, they were always so; thus, Locke talks of the *invention* of sciences. As commonly used, the first word signifies the formation of something which would not necessarily have existed, but for the invention; the second means the finding out that which always did exist, and would have existed whether the discovery had been made or not. We all perfectly see the error in the assertion, set down for correction in the English exercise-books, that "Galileo *discovered* the telescope, and Harvey *invented* the circulation of the blood;" and also the propriety of the assignment of words made by Macaulay, when he says that the terms in which Machiavelli is usually described would seem to import that he was "the discoverer of ambition and revenge, the original inventor of perjury." We can imagine the possibility of a telescope having never been framed, or a false oath having never been sworn; but so long as man exists his blood will circulate, and feelings of ambition and revenge will spring up in his mind. The words have some analogy with those of problem and theorem in geometry: and particularly in this, that invention must be ultimately a suggestion of discovery. The inventor of modern ink, which till his time had never existed, discovered that a mixture of galls and sulphate of iron would produce a durable dark fluid: his invention consisted in the application of his discovery to the art of writing. In this manner it may be asserted by some [BACON, ROGER, in BIOG. DIV.] that Roger Bacon discovered the telescope. There must be a discovery preceding every invention; but it does not follow that every discovery leads to invention. But yet there are some cases in which the preceding definitions fail to describe the actual use of words: for example, bichromate of potash was never found in nature, never discovered; its elements were compounded in the laboratory by its inventor. But the chemists would not call this an invention, nor anything but a discovery; we should recommend them to draw the distinction, as useful to the memory in relation to the history of their science.

There is in the words discovery and invention a tempting resemblance, often just and often fallacious, to those of theory and practice. But in fact each of the things must be subdivided into theoretical and practical. The effect of the non-spherical form of the earth upon the moon's motion was discovered theoretically; the variation and the evection were discovered practically. As to inventions, we call Davy's safety lamp a theoretical invention: for the question given was how to overcome a certain danger, generally; and it was not even assumed that a lamp was to be constructed. But the common story of the boy who saved his labour by tying a string from the valve he was employed to open and shut to a part of the machinery which moved in such a manner as to do it for him, is, if true, a record of a practical invention. Still there is truth in this, that practical men, properly so called [THEORY AND PRACTICE], have invented oftener than they have discovered; and that theoretical men have discovered more often than they have invented.

It is no wonder that the early history of discovery should be confused and uncertain: the loss of documents, which operates on all our first knowledge of antiquity, is a sufficient explanation. Nor is it surprising that first writers should be persons of unsettled claims; that in the case of Euclid, for example, we should not be so well able to say where his discoveries began as where they ended. But it does seem strange that in matters of our own day, or of that immediately preceding, it should be a question to whom a right of discovery should belong, when the only tangible matter is a book, to the date of the publication of which there is every possible attestation.

There is one most important preliminary consideration, which will, in the minds of those who for the first time give it due attention, change the face of the whole question. When the period arrives at which a discovery becomes possible, there are many courses which lead to it, and many ships sailing on each of these courses. The analogy may be carried further. When a new island is discovered in or near a frequented track, so soon as a ship of some one country casts anchor in a port and takes possession, it may be afterwards found in some logs that something like land had been suspected before, in others that land birds had been seen, in others that the colour of the water was noted, in others that an alteration of the current was observed, and so on, all near the same point, and any one of which might have led to the discovery, if the hint had been followed. It is the same in matters of science, to an extent which will not be easily credited by those who are unacquainted with its history. And this greatly enhances the merit of most original researches. It is much to the credit of Newton that Huyghens had gone so far as to determine the conditions of circular motion, that Grimaldi had noted the effect of the prism on light, that Fermat and Cavalieri had all but discovered the method of fluxions. The character of accidental good fortune disappears when we see that the progress of knowledge seems to bring new results within the possible reach of many, but within the actual grasp only of one. Is there then nothing accidental in discovery and invention? We answer that there is something, but that the accidents which *might* produce discovery are happening to all, and frequently; while the accidents which *do* produce it happen to those only who are ready to take advantage of them. But this, it may be said, is reasoning in a circle; for if we are asked how we distinguish the person who is ready to take advantage from the one who is not, we have only the discovery to point to. We reply, that it generally happens that the persons who can thus fix a casualty, are also those who give evidence of successful research in cases where fortune shows no special favour. It was by a mere accident that Mr. Baily [FLAMSTEED; BAILY; in BIOG. DIV.] bought a house opposite to the possessor of a large bundle of Flamsteed's letters, and nothing more that the fact of their existence came to his ears. Many perhaps had seen them, and either taken it for granted that the contents were all in print, or been unable to judge of their value. But the life of Flamsteed is not the only evidence of Mr. Baily's success in a point of astronomical history: there was no accident about the editorship of the old catalogues. It is said to have been by a casual effect of sun-light at a window that Malus discovered the polarisation of reflected light; but then Malus was a profound optical investigator. It is our conviction that no accidents are valid except those which happen to the proper men at the right times; and that there are usually other means of showing this besides the success of the accidents themselves.

Before we can examine the title to a discovery, it must first be settled what the discovery is: and this is frequently the greatest difficulty. The case of the steam-engine is constantly under discussion; and the principal point at issue is, what is the steam-engine. Heron of Alexandria certainly produced rotatory motion by steam, and with sufficient funds, could have ground all the corn in Egypt by his method. If we assign the merit to the person who contrived such an economy of fuel as to place the use of steam on something like its present footing of convenience, it then becomes a doubt whether any except Watt has a claim. M. Arago remarks on this subject, that a watchmaker would be struck dumb by the question, who invented a watch? The thing as it now exists is not the invention of any one person. So long as there is any national feeling in the discussion, one or another definition will be proposed, constructed to suit the advocacy of one or another claim. We have not here to settle the cases which we cite; it is enough that they illustrate our point.

It may happen that in a complicated instrument or method, the perfecting of which extends over a long period, there is some one distinguishing characteristic the introduction of which marks the main epoch of the invention. In the case of the watch, for instance, if we ask for the distinctive definition of the term, we find that it is not merely an instrument for measuring time, which would include the clepsydra. nor an application of wheel-work for that purpose, which would include the clock; but it is the use of a spring for the regulator in which consists the distinction between a watch and other horologes. In a similar manner we look upon the additions made by Vieta to the mechanism of algebra as constituting the main groundwork of what now bears the name. But it would be exceedingly wrong to say that Hooke invented a watch, or that Vieta invented algebra: things done before and after both essentially belong to the ideas we mean to convey by the words. But it is not an uncommon practice of writers to strip a word of all its accessories, and to attribute (justly enough perhaps) the invention so cut down to some one person, and then to clothe the word with all its most modern associations, and the favoured inventor with all the glory which ought to be divided among many. When the steam engine is reduced to a tea-kettle, or at most to a pump, it is Avery, or De Caus, or Worcester, or Newcomen, or Papin, &c., &c., who invented it, according to the country or the fancy of the writer; but when once the claim is established, the tea-kettle throws out a condenser, and the pump runs along the railroad at sixty miles an hour.

The common sense of the law requires that the applicant for a patent should make a distinct specification, not merely of what he intends to construct, but of that particular part of the contrivance which he claims as his own; and here a claim upon anything old, or an omission of anything new, vitiates the patent. [PATENT.] The cases which have occurred under this law would be good study for those who write on discovery.

It may indeed happen that the amount of claim may be materially augmented by the view which the discoverer takes of his own title. Columbus inferred, on true principles, the possibility of crossing the Atlantic, spent the energies of a life in procuring the means of making a trial, and is therefore properly and truly the discoverer of all the new world: the Northmen who had visited it long before did not promulgate their discovery, and it might as well be given to the aboriginal inhabitants of the continent itself as to them. It does not depreciate the merit of Columbus that he could not but suppose he should reach India or China: these were the certainties at which he aimed, and which he would have reached had he not been stopped by the intermediate continent which ought to bear his name. Had Heron, when he first announced and executed his revolving boiler, been able to point out that it was a method of producing force from fuel, which might supply the place of human labour—that all which remained was adaptation—and that skill in the use of this new kind of force would make it a substitute for the strength of men and beasts—it would have been difficult to have denied him the title of the discoverer of the steam-engine, and the inventor of the first step.

Among the consequences of attempting to describe discoveries under too general terms, is this, that both things and persons are allowed to clash unnecessarily. It is not always, to be sure, that this goes such a length as procuring for Dalton's atomic theory the character of being a republication of the notions adopted by Epicurus from his predecessors; if it did there would be less harm: there are many theories between which mischievous confusion is more easily brought about than between those of the philosophers of Athens and of Manchester. The nomenclature of science is perplexed by phrases of no precision—as that Newton discovered gravitation, instead of a true explanation of the heavenly motions by means of *universal* gravitation—that he first advanced the true theory of astronomy, which he did in one sense, and Copernicus in another; whence the provinces of the two are frequently confounded. It must also be noticed that a mere opinion, the result of choice between several, one or other of which must have been taken, is confounded with the same opinion advanced and supported by reasons. Thus Philolaus and Aristarchus asserted the motion of the earth, and Copernicus is said to have only revived their opinion. The difference between the two cases lies in this, that the ancient philosophers merely asserted their belief, the modern one made his hypothesis the means of accounting for all the known motions of the heavens, diurnal, annual. and precessional.

The specification, to borrow a term, having been agreed upon, the next question is, what constitutes a claim to discovery? The answer is priority of publication. If, as has often happened, two persons should discover the same thing about the same time, the one who first publishes is universally recognised as the discoverer; for 'discoverer' either implies priority, or is an abbreviation of the words 'first discoverer.' Of course if a fraud can be proved, if it can be satisfactorily shown that the first publisher stole his matter from another, he would not be allowed the advantage of his wrong: but the onus of proving the fraud lies entirely upon the assertor of it, and, until the evidence and verdict arrive, the first publisher is in possession. The reasons for this rule are not altogether those which exist for the rule in law. The objects of the latter are the protection of private rights and public peace; or rather the assignment of private rights in such a manner, as best, in the long run, to promote the welfare of the community, and particularly its peace, without any great shock to the natural feelings of equity. It is not difficult to conceive a class of cases in which men would gladly give up a small per centage of decisions consonant to natural justice, or what is so called, for the sake of a rule which would present decided advantages as a rule, in the imperfect state of private morality. But the object of the scientific historian is truth for its own sake; he has nothing to do with conventions made for the sake of peace.

This rule, that first publication gives the right, until the contrary is proved, is adopted for the sake of its own probability as a starting point. Select at hazard the name of a result, and of its first announcer; no doubt will exist in the mind of any one, used to the history of science, that it is at least fifty to one the name of the real discoverer is thus given. But if it be *the fact* that the discovery was made at an earlier period, and if that fact can be established, the history of the human mind must not be falsified by adherence to a rule. If, for example, it could be made out, from internal evidence, that Archimedes must have had an algebra and a differential calculus, which deference to the notions of his time prevented him from publishing, it would never do to let the formal claims of Leibnitz and Newton prevent the allowance of that of Archimedes: for then would result the suppression of the actual fact, which, if true, would be of great consequence, namely, that the Greek mathematics were powerful enough to lead their best minds to the discoveries of modern times. We insist upon this because we have observed a considerable tendency in writers of history to establish a rule on legal grounds of peace and convenience. There is also a confusion between two distinct things; the claims of history, and the claims of the individual: the former demands true facts, the latter just appreciation of his merit. By a perversity of the human mind, Newton and Leibnitz would lose fame to-morrow, more or less,—that is, more with some and less with others —if an undoubted manuscript of Archimedes were to turn up, showing that he possessed a formal differential calculus. We are apt to assign praise to mere priority, independently of originality, and to withdraw it on failure of priority. But it is forgotten that the merit of priority only lies in this, that the earlier an invention or discovery is made the ruder are the methods and instruments, and the fewer the hints to which it is due. For example, D'Alembert re-invented Taylor's theorem [TAYLOR, in BIOG. DIV.] in, or shortly before, 1754. He has all the merit due to the discovery, as in 1754. But could it now be proved that Taylor's works, &c., were recent forgeries, so that D'Alembert should stand as the original inventor, it would be impossible to put him in Taylor's place; the differential calculus was in two very different states in 1716 and in 1754.

There is also an injurious tendency to stand by the fixed rule as a thing of good consequences, in the way of punishment or stimulus: and certainly there is no denying that if it were but right to substitute in history the thing which is not for the thing which is, there are advantages arising from the adoption of the rigid rule of first publication. Tartaglia [TARTAGLIA, in BIOG. DIV.] suppressed his method for cubic equations from a selfish motive: Cardan, to whom he had communicated it under promise of secrecy, published it, with a sufficient acknowledgment; nevertheless the rule always goes by Cardan's name. There is little to regret here: Tartaglia was willing, simply that he might be able to puzzle his contemporaries, to retard the progress of algebra; it is not certain that he ever would have published his discoveries. The public has rewarded the individual to whom they were indebted for knowledge by affixing his name to the rules he announced. If it were understood that the name attached to any scientific result was always that of the first publisher, saving all the rights of history over the truth of the discovery, this and similar acts of nomenclature might be a satisfactory use of the *norma loquendi*. It has sometimes happened that individuals have deposited sealed packets with public scientific bodies, to preserve their rights in the event of any one else arriving at results which they wished to avoid making public until they had followed them out to their remote conclusions. This practice is one which would not prevent the name of any other person from being attached to the contents of the packet, if he came independently by the same results, and published them before the packet was opened, though unquestionably the packet would prove the privity of the depositor.

The next question is, what constitutes a sufficient publication. And here the answer is, that the only mode which can give the discoverer no further duty in the matter, is the press. If any one should prefer written correspondence, public lectures, or oral conversation, it must be at his own risk. A printed book, pamphlet, magazine, or newspaper which any one who likes may buy, is a record of the court of history from the day of its appearance: but any other mode of communication, which is of its own nature not addressed to the public at large, must be put in and proved before it can be available. A communication to a scientific body, for example, is only so much better than a letter to a friend, as it is more public and more easily proved: but unless it be published in the transactions of that body, in which case it ranks with a book from the date of publication, it will require subsequent establishment. There is, however, always a difficulty with regard to such communications, particularly when the transactions of the academy in question do not appear till some time after the reading of the memoir. It is impossible to know what an author has added as the paper went through the press: that is, if a contest of dates should arise, it will always be necessary to assume the date of publication, unless some proof can be given that the memoir as published is, in the matter under dispute, the same as that which was originally communicated. It has happened before now, that a communication presented has been almost entirely remodelled before it was printed. We have little doubt that, in course of time, bodies which publish transactions will find it necessary to require that authors should either print their communications as presented, or date such additions as they feel desirous of making. Since these remarks were first written, some of the scientific societies have enforced attention to these points.

The most remarkable question of publication that ever arose was that relative to the invention of fluxions. [FLUXIONS; COMMERCIUM EPISTOLICUM.] There never was a case in which it was more necessary to consider the rights of history, and not to judge by any fixed rule. Newton, unquestionably the first inventor, made no publication whatever at the time: an anagram, or transposed sentence, cannot be looked upon in any other light than as a sealed packet. Leibnitz has accordingly the full merit of an inventor, and priority of publication. Newton has given proof that he could have published it, if he had chosen. He is the first inventor; Leibnitz is the benefactor of the world.

It frequently happens, as before observed, that independent discoveries take place about the same time: there is no doubt that such is the fact. When the publications take place very nearly at the same time, particularly when they are in different countries, it is easy enough to admit the real independence of the two. If the same thing should appear in the notices of the Royal Society and the Comptes Rendus of the French Institute within a few weeks of each other, the presumption is strong in favour of neither writer having had a communication, directly or indirectly, from the other: and this presumption must be rebutted by any one who desires to prove plagiarism. But as the interval of time becomes greater, the presumption, so far as it is derived from time only, is weakened. In such a case, the internal evidence of the writings themselves must be carefully looked at. There is usually a very great difference between the modes in which different investigators arrive at, and even in which they state, the same conclusions: those who would do a dishonest thing might know this as well as others, and might endeavour to counterfeit originality. To detect the base metal is not always easy: to prove its baseness is next to impossible. But it mostly happens that really independent investigators carry their results to different lengths; one will go further in one part of the subject, another in another.

As may be supposed, the most disputed cases are national ones; including in that term the schisms of different classes in the same country, as the scientific feuds of universities, of literary societies, &c. And between people of different countries and governments, the question arises in two distinct ways, not only as to the definition of the discovery itself, and the priority of publication, but as to the country to which the discoverer is to be said to belong. And here there seems to us to be a necessity for a distinction which is rarely made, and no wonder; national pride is the mortal enemy of discriminative argument. All people like to believe that their race is gifted by nature with talent, and that their public policy is calculated to draw it out. For proof of this they appeal to their great writers and thinkers, among whom they include all whom they have drawn into their country, and all whom they have driven out. Now it is clear that the eminent men who have been induced to settle in a country not their own, may be a credit to the institutions, but can be none to the race, of their adopted country; while those who are driven away may do honour to the race but not to the institutions of the land from which they are exiled. Take the cases for instance of Lagrange and De Moivre. Lagrange, who, of many offers made to him when he left Prussia, preferred that of the king of France, resided in that country from 1787 till his death in 1813, was exempted from the expulsion of foreigners ordered by Robespierre, and received, during all governments from the old monarchy to the empire, every possible honour and aid,—is a greater credit to French institutions and feelings than if he had been born in their country. But so far as blood is concerned, he is almost wholly Italian, having been born, and established his first reputation, at Turin: his mother tongue was Italian, and his first work was published in Italian. It is said, we do not know on what authority, that his great grandfather was a Frenchman, which may entitle France to claim the eighth part of him. De Moivre, on the other hand, born of French parents and educated in France, was driven from his country by religious fanaticism, and none of his works were published either in France or in French. Whatever credit his talents may do to his race, he is the disgrace of their institutions, as to the time in which he lived. Not that he received such encouragement here as would entitle us to say that the honour lost by France was wholly gained by England. While picking up a scanty living by private teaching, the only way in which he could find time to read the Principia was by tearing it leaf from leaf, and carrying a leaf in his pocket to look at while walking from one pupil to another, or at any other chance interval.

There is much absurdity in the mode by which national prowess in matters of discovery is tested. A few of the very first names are made the only subjects of comparison. There is some presumption, certainly, that the great names are the best of many, and that the plants are most numerous where the largest plants are found. But this presumption must not be urged when an attentive consideration will settle the question without it. Archimedes was the greatest of the Greek mathematicians; but Sicily was not therefore the most celebrated in science of all the countries in which Greece had colonised. So far from it, that when in the sixteenth century Maurolico lived and wrote, the following epigram was made upon him—

> Te quoque Zancla tulit, Maurolyce, ne sit in uno
> Clara Syracosio Sicelis ora sene.

The most difficult question of all is undoubtedly what degree of merit belongs to a discovery, and the settlement of the question where in the list it places its author. The public in general judges by utility; whereas it is notorious that many discoveries show more power of mind than others of much greater value to the world. The rule of utility is a good one for mankind in general; but it must be taken with modification by the historian of science. Who has most benefited his species, and who has shown himself most above his species in intellect, are two different questions. The merit of the inventor, and his genius, are not comparable quantities. The merit is determined by the study, the personal risk or inconvenience which it was requisite to undergo, the patience and perseverance which must have been shown, and the goodness of the motive which appears to have actuated. The genius is the greater the less the pain and labour, and is wholly independent of moral considerations. A patient schoolboy who multiplies one number by another with time and care, has more merit than the wonderful youths who have sometimes appeared, and who can do it in their heads; but the first has far less mental power, in this one line, than the second. All these things are plain on the first statement; but they are far from receiving due attention, and will so remain until the history of discovery is written without too much deference to popular reputation.

We may mention, as a thing to be guarded against, the disposition to depreciate a discovery because it is not something more than it pretends to be, which is frequently combined with a wish to judge of its merit by an arbitrary *à priori* standard of what it ought to have been. Sturm's theorem is a very pretty instance. Before it appeared, a purely theoretical and strictly certain method was eagerly sought after, and any such, however difficult, would have been held a great gain. The object is at last attained, but in a manner which is troublesome to use. To look at the way in which some writers now mention it, one would suppose they had entirely forgotten how many investigators of the first order had given up the subject without producing any method at all.

Since the preceding article was published, many confirmations have arisen of our assertion that for the most part discoveries are made by more than one person when the right time arrives. The eighth satellite of Saturn was discovered on one and the same day in England and America; and several of the smaller planets, those specks of which there are hundreds, perhaps thousands, in our system, have been twice announced within a few days by observers of whom the second was ignorant of the success of his predecessor. But the most remarkable case of simultaneous investigation which ever occurred was the solution of the inverse problem of gravitation by Leverrier and Adams, which resulted in the discovery of NEPTUNE by Galle, at Berlin, on information furnished by Leverrier. It is not our intention to enter on this celebrated case: we shall only make a remark on the discussion which it produced. [ASTEROIDS.]

It soon became apparent that in the scientific world, both of England and France, the word *publication* retains its old meaning, though in common language it now means circulation by help of the press. To publish is, in science as in law, to make known to others, no matter how. Some little disposition was shown by a few to confound publication, the genus, with printing, the species; but without producing any general assent. And a reference was made to *Waring's rule*, a phrase of which we gave no explanation in the preceding article. We proceed to supply this omission, because we have since heard it cited as the rule to which men of science appeal in matters of priority. They follow, it is said, the rule laid down by Waring, that the first publisher is to be held the discoverer: and it is frequently insisted that this word publication is used in the modern and restricted sense.

Waring ('Medit. Analyt.' pref. p. ii, 1776) speaking about a claim of John Bernoulli to something which had been shown both by Newton and Leibnitz, as having been found by himself before he had seen their writings, speaks as follows:—

> "Sed nemo potest esse testis in suas partes, is mihi semper dicendus est inventor, qui primus evulgavit, vel saltem cum amicis communicavit, vix enim inveniatur aliquis, dignus mathematici nomine, qui de suo ingenio multa scriptorum priorum reperta haud detexit."

That is to say, Waring held the inventor to be the first who *evulgates*—tells to all, no matter how—or at least tells to his own friends. And in truth even these conditions are not so much Waring's rule, as Waring's examples of the way in which discovery may be proved under his rule. That rule is implied in his opening dictum, that no man may be his own witness; that is, evidence distinct from his own, and sufficient without it, must be produced. And this is common sense. A man must prove that he is the discoverer: it is not enough to prove that he is either the discoverer, or a self-deceiver or a rogue.

For ourselves, we admit no right in any one to lay down a rule: or if we should be pressed to state some rule, we can only say that we hold by the rule in Chrononhotonthologos:—

> "Go! call a coach! and let a coach be called!
> And *let the man who calleth be the caller!*"

Let the man who discovers be held the discoverer; and let evidence settle who that man is: and let evidence be that which makes knowing and reflecting men believe; we know no other definition. And if knowing and reflecting men be seriously divided in opinion, let it be held undecided who is the discoverer. The reason of this rule is that it always has been the rule, is, and always will be the rule. The attempt to lay down a law of assignment of discovery has not succeeded: the law is quoted with respect until a dispute arises, and then *all* the facts of the case are discussed, which is tantamount to a downright refusal to obey the law. For it is to be observed that the rule of first publication is of no import except in its negative or prohibitory character. That the first publisher, no other fact except first publication being on the record, shall be held the discoverer, needs no reduction to rule: it is mere conclusion of course. The asserted rule means that first publication shall exclude from the discussion all other considerations of fact, or shall be conclusive against them, if introduced. This it never has been, and never will be.

INVENTORY. [EXECUTOR.]

INVERSE, INVERSION. Any two operations of algebra are said to be inverse when one of them undoes, so to speak, the effect of the other; so that if both be successively performed upon the same quantity, the result is that quantity itself. For instance, the operations implied in $1+x^2$ and $\surd(x-1)$ are inverse to one another; for

$$1+\left\{\sqrt{x-1}\right\}^2=x, \qquad \sqrt{(1+x^2-1)}=x.$$

We need do no more than name addition and subtraction, multiplication and division, raising of powers and extraction of roots, as pairs of inverse operations.

The operation of inversion is the solution of an equation and *vice versâ*. Let it be required to find the operation inverse to ϕx. Assume $\phi x=y$, and find x in terms of y; say $x=\psi y$, then $\phi(\psi y)=y$, or ϕ and ψ are inverse operations. Thus if $x^2-2x=y, x=1\pm\sqrt{y+1}$, and either of the two, $1+\sqrt{x+1}$, or $1-\sqrt{x+1}$, is inverse to x^2-2x.

It thus appears that a function may have more than one inverse function, and there are functions which have an infinite number; but there is a distinction by which one may be separated from all the rest. Let the Greek letters in this article be all functional symbols, or marks of operations to be performed, and let them come before the subject of operation, the quantity x, or y, &c., in the order in which they are to be performed. Thus $\alpha\phi x$ denotes the result of performing the operation ϕ upon x, and then the operation α upon ϕx. Now let $\phi x=z$ give $x=\psi z$, where ϕx is an unambiguous operation, and ψz is, generally speaking, ambiguous, or presenting several different forms. Then ϕ and ψ are inverse operations, and $\phi\psi z=z$, and we might suppose at first that $x=\psi\phi x$; that is to say, we might imagine that ψ destroys ϕ as well as that ϕ destroys ψ. But since ψ is ambiguous, it may be that only one or more of the forms of ψ will satisfy $x=\psi\phi x$, and not all; and that this will be the case with one is obvious, while we can show that it cannot happen with more than one. For though the same operation, performed on different functions, may produce the same function, yet different operations, performed on the same function, must produce different functions. If then α and β be different forms of ψ, we have $\phi\alpha x=x$ and $\phi\beta x=x$; but we cannot have both $\alpha\phi x=x$ and $\beta\phi x=x$, where α and β are different, ϕx having absolutely the same form and value in both equations.

From all the inverses of a function ϕx, then, we separate that one, αx, which gives both $\phi\alpha x=x$ and $\alpha\phi x=x$, and call it the *convertible* inverse. Its symbol is ϕ^{-1}, so that $\phi^{-1}x$ means that operation which satisfies both the equations $\phi\phi^{-1}x=x$ and $\phi^{-1}\phi x=x$. [EXPONENT.] In the preceding example $1+\surd(x+1)$ is the convertible inverse of x^2-2x: for $1+\surd(x^2-2x+1)=1+x-1=x$. But $1-\sqrt{x^2-2x+1}$ gives $1-(x-1)$ or $2-x$; and we call $1-\surd(x+1)$ an inconvertible inverse.

Every function which has more than one inverse is not only a function of x, but the same function of other functions of x. Let αx be an inconvertible inverse of x; then $\alpha\phi x$ is not x, let it be ωx. Then $\phi\alpha x$ being x, $\phi\alpha\phi x$ is ϕx, or $\phi\omega x$ is ϕx, so that ϕx is the same function of ωx which it is of x. Thus in the preceding example x^2-2x is the same function of $2-x$ which it is of x; or

$$x^2-2x=(2-x)^2-2(2-x).$$

We have then this theorem: every function has as many different forms as inverses, and all these forms can be made by writing different functions of x instead of x in the original function; and each inverse of the function is the convertible inverse to one of its forms, and an inconvertible inverse to all the rest. Thus $1-\surd(x+1)$, which is an inconvertible inverse to x^2-2x, is the convertible inverse of $(2-x)^2-2(2-x)$: for

$$1-\surd\left((2-x)^2-2(2-x)+1\right)=1-(2-x-1)=x.$$

The way to make the convertible inverse of a given function find all the rest is as follows. Find the solutions of the equation $\phi\,\omega\,x=\phi\,x$, and let them be $\omega_1\,x, \omega_2\,x$, &c. Then $\phi^{-1}x$ being the convertible inverse of $\phi\,x$, the remaining inverses are $\omega_1\,\phi^{-1}x$, $\omega_2\,\phi^{-1}x$, &c. Thus in the preceding example $\phi^{-1}x$ being the convertible inverse, the other is $2-\phi^{-1}x$. [PERIODIC FUNCTIONS.] There is a remarkable class of functions, each of which is its own inverse, such as $1-x$, $\frac{1}{x}$, $\sqrt{(1-x^2)}$, &c. Now if $\phi\,x=\phi^{-1}x$ we have $\phi\,\phi\,x=x$, and these functions will be considered, in the article just cited, as periodic functions of the second order.

The equation $\phi\,\phi^{-1}x=x$ being understood, suppose that between the first and second operations we interpose the operation α, so that we have $\phi\,\alpha\,\phi^{-1}x$. This is no longer equal to x, but it is a function, the properties of which are closely connected with those of $\alpha\,x$. For instance, if $\alpha\,x$ and $\beta\,x$ be inverse to each other, then $\phi\,\alpha\,\phi^{-1}x$ and $\phi\,\beta\,\phi^{-1}x$ are also inverse to each other: for $\alpha\,\beta\,x=x$ and $\phi\,\alpha\,\phi^{-1}\left(\phi\,\beta\,\phi^{-1}\right)x$ is $\phi\,\alpha\,\phi^{-1}\,\phi\,\beta\,\phi^{-1}x$, or $\phi\,\alpha\,\beta\,\phi^{-1}x$, or $\phi\,\phi^{-1}x$, or x. Thus knowing $x+1$ and $x-1$ to be inverse functions, we know immediately that $\log(\epsilon^x+1)$ and $\log(\epsilon^x-1)$ are inverse functions; and also $\sqrt{(x^2+1)}$ and $\sqrt{(x^2-1)}$. For more detail on this subject see the article 'Calculus of Functions,' in the 'Encyclopædia Metropolitana.'

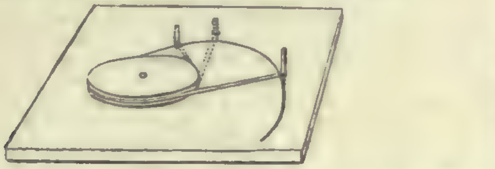
INVERSION, in Music, is a change in the relative position of two sounds, or of the several notes of a chord. Thus, C D, an interval of a 2nd, becomes by inversion (D C) a 7th. Example,—

And C E G, the notes of the triad, or perfect chord, by inversion become the chord of the 6th (E G C), or of the $\frac{6}{4}$th (G C E). Example,—

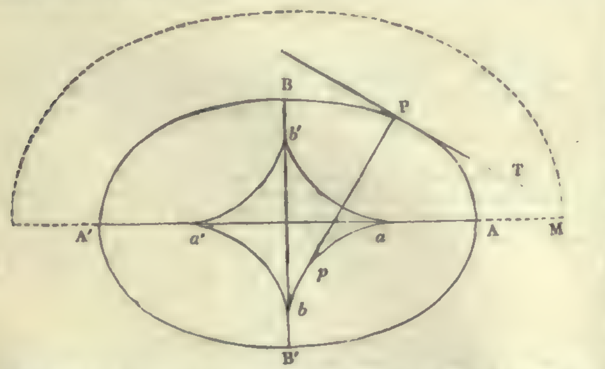
For other musical inversions, see CANON and FUGUE.

INVESTITURE. [FEUDAL SYSTEM.]

INVOLUTE AND EVOLUTE (the curve unrolled and the curve from which it is unrolled), a name given to two curves so formed and placed, that supposing the second to be cut out from solid matter, the first can be formed by fastening one end of a thread upon a point in the second, attaching a pencil to the other end, and moving the pencil so that the thread may either gradually enwrap or be unwrapped from the curve to which it is fastened. Thus the pencil in the diagram is describing the involute of a circle, or the curve of which the circle is the evolute. But the evolute of a circle is evidently a point.

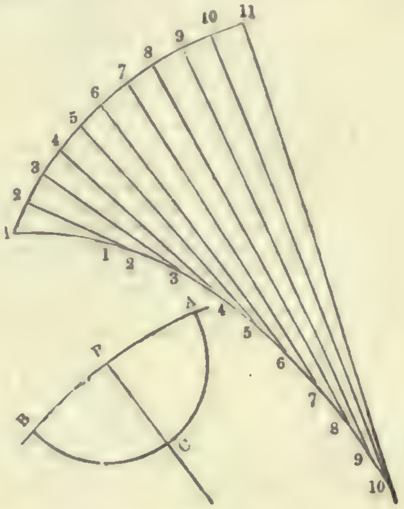


The following figure represents an ellipse with its evolute. If the thread be fastened at b, wrapped over $b\ a$, and continued to A, it will, as it unwraps from $a\ b$, describe the arc A B; and B A′ while it wraps over $b\ a'$. If fastened in a similar manner at b', it will by the same process describe A B′A′.



If the line p P be drawn tangent to the evolute at p, it is one of the positions of the thread, and P T, the tangent of the involute at P, is perpendicular to p P. Also p P is the radius of curvature of the involute at P; this is to say, no circle can pass so near the curve at P, as the one which has p for its centre and p P for its radius. [CURVATURE.] Also, any arc of the evolute is the difference of two radii of curvature of the involute: thus the arc $a p$ is the difference between a A and p P. Such are the principal geometrical connections of the two curves.

Every curve has one evolute, and an infinite number of involutes. For instance, fastening the thread at b, and continuing it to M instead of A, we may with the cheeks $a\ b$ and $b\ a'$ produce another involute from them (represented by a dotted line); and any number, however great, by varying the position of M. But none of these involutes will be ellipses, except the one from which the evolute was made; though they will all be ovals having remarkable analogies with the ellipse. The proper name for curves described from the same evolute is *parallel curves*, since they have the fundamental property of parallel lines: for they never meet, though (if they admit of it) ever so far produced; a straight line perpendicular to one is always perpendicular to the other; and the part of the perpendicular intercepted is always of the same length. When arcs of parallel curves are required to be laid down, the most commodious method of proceeding is to construct the evolute of one of the arcs approximately, as follows. On the arc draw tangents at moderately small distances, and draw perpendiculars to those tangents. The parts of the tangents cut off from each by its neighbours will together give the arc of the evolute near enough for all purposes. And it may be well to notice that it will be a sufficiently accurate method of drawing the perpendicular to the tangent at a point P, if we take a small circle whose centre is P, bisect the arc A C B in C, and join and produce P C.



The angular error thus committed is only a small portion of the angle made by the tangents at P and A.

Whenever the two arcs adjacent to a normal (or perpendicular to the tangent) of the involute are equal and similar, there is a cusp in the evolute; and the evolute generally recedes without limit as we approach a point of contrary flexure in the involute.

The mathematical method of finding the evolute is as follows. Let $y=\phi\,x$ be the equation of the involute, and let X and Y be the co-ordinates of the point on the evolute corresponding to that on the involute whose co-ordinates are x and y. Form the three equations—

$$y=\phi\,x;$$
$$X-x+\frac{dy}{dx}(Y-y)=0;$$
$$1+\left(\frac{dy}{dx}\right)^2-\frac{d^2y}{dx^2}(Y-y)=0;$$

and from them eliminate x and y. The resulting equation between X and Y is that of the evolute. But if the evolute be given, and the involute is to be determined, let $Y=f\,X$ be the equation of the former, and from this and the latter two of the preceding three equations eliminate X and Y. There will result a differential equation of the second order between y and x, among the primitives of which is the equation of the involute. But the differential equation of the involutes is one of the *singular* primitives of this equation of the second order, and the question is most easily treated in the following way. Find the differential equation of the curves which cut all the tangents of the given evolute at right angles: those curves are the involutes required.

Thus if the curve be a parabola having the equation $y=c\ x^2$, the equations for determining the evolute are—

$$y=c\,x^2;$$
$$X-x+2\,c\,x(Y-y)=0;$$
$$1+4c^2x^2-2\,c\,(Y-y)=0;$$

from which we find—

$$X=-4c^2x^3,\qquad Y=\frac{1}{2\,c}+3\,c\,x^2;$$

which give $Y=\frac{1}{2\,c}+\frac{3}{2}\left(\frac{X^2}{2\,c}\right)^{\frac{1}{3}}$.

the equation of the evolute of the parabola, which evolute therefore appears to be what is called a *semi-cubical* parabola.

For considerations similar to those which precede see CAUSTICS.

INVOLUTION and EVOLUTION (Arithmetic). Taking these words in their etymological sense, they might stand for the greater part of mathematical analysis. In their technical algebraical sense, they mean only the raising of powers, and the inverse operation, the extraction of roots. The revival however of a general process, accompanied by an improvement which makes it comparatively easy, renders it necessary to make a more extensive definition of the terms. We shall not relinquish any characteristic of the old meanings, and shall bring all corresponding processes together, by laying down the following definition :—Involution is the performance of any number of successive multiplications with the same multiplier, interrupted or not by additions or subtractions; and evolution is any method of finding out, from the result of an involution, what multiplier was employed, provided that the said method proceed by involutions. Thus to determine $2x^3+4x^2-3x+10$ by involution, we multiply 2 by x and add 4; then multiply by x and subtract 3, then multiply by x and add 10. If this give 1000, then any method of determining x which proceeds by successive involutions is evolution.

Forty years ago our only instances of evolution would have been common division, and the extraction of the square and cube roots, with references to Vieta, Harriot, Oughtred, and the older algebraists in general, for evolutionary methods of solving equations, bearing a strong likeness to such extractions. But since the publication of Mr. Horner's 'New Method of Solving Equations of all Orders,' 'Phil. Trans.,' 1819, the process which has rendered it worth while to propose the preceding extension of terms has been in the hands of mathematicians. For a more detailed account than we can here give, the reader is referred to the paper just cited, which is reprinted in the 'Ladies' Diary' for 1838, or to 'The Theory and Solution of Algebraical Equations,' by Professor Young, of Belfast (London, J. Souter, 1835).

We should begin with simple division, and the extraction of the square and cube roots, if we were writing an elementary treatise. But taking it for granted that the reader is familiar with the first two, at least, we shall proceed to describe the general process. This consists of three distinct parts, the first two of which have been long known, while the third, which contains the peculiar distinction of this method, is due to Mr. Horner.[*]

1. In the article APPROXIMATION it is shown that if a be a value of x which makes ϕx very small, then $a-(\phi a \div \phi' a)$ is a value of x which makes ϕx much smaller; so that a continued succession of approximations may be made to a value of x which makes ϕx absolutely $=0$. Here ϕx means the differential coefficient or derived function, and if

$$\phi x = Ax^n + Bx^{n-1} + Cx^{n-2} + \ldots\ldots;\ \text{then}$$
$$\phi' x = nAx^{n-1} + (n-1)Bx^{n-2} + (n-2)Cx^{n-3} + \ldots.$$

2. Meaning by a root of ϕx, any value of x which makes $\phi x=0$, it is obvious that $\phi(x+a)$ is a function which has for its roots the roots of ϕx, each diminished by a. And the substitution of $x+a$ instead of x in the preceding value of ϕx gives a well known development, of which an instance will be more to our present purpose. Let the function be

$$Ax^5 + Bx^4 + Cx^3 + Dx^2 + Ex + F \ldots. (1).$$

Write $x+a$ for x, and this becomes

$$Ax^5 + (5Aa+B)\,x^4 + (10Aa^2+4Ba+C)x^3 + (10Aa^3+6Ba^2+3Ca+D)\,x^2$$
$$+ (5Aa^4+4Ba^3+3Ca^2+2Da+E)\,x + Aa^5+Ba^4+Ca^3+Da^2+Ea+F\,;$$

which we may represent by

$$Ax^5 + \phi_4 a\,x^4 + \phi_3 a\,x^3 + \phi_2 a\,x^2 + \phi' a\,x + \phi a.$$

3. The quantities ϕa, $\phi' a$, $\phi_2 a$, &c., may be determined by a succession of involutions, each one making use of the results of the preceding. Find ϕa by involution, of which the following are the steps :—

$$\begin{array}{l}
A \\
Aa + B \\
Aa^2 + Ba + C \\
Aa^3 + Ba^2 + Ca + D \\
Aa^4 + Ba^3 + Ca^2 + Da + E \\
Aa^5 + Ba^4 + Ca^3 + Da^2 + Ea + F = \phi a
\end{array}$$

Repeat the process, using the preceding quantities, except the last and we have $\phi' a$ by the following steps :—

$$\begin{array}{l}
A \\
2Aa + B \\
3Aa^2 + 2Ba + C \\
4Aa^3 + 3Ba^2 + 2Ca + D \\
5Aa^4 + 4Ba^3 + 3Ca^2 + 2Da + E = \phi' a.
\end{array}$$

A repetition of the process, leaving out the last, gives $\phi_2 a$, as follows :—

$$\begin{array}{l}
A \\
3Aa + B \\
6Aa^2 + 3Ba + C \\
10Aa^3 + 6Ba^2 + 3Ca + D = \phi_2 a.
\end{array}$$

Repetition gives $\phi_3 a$, and finally $\phi_4 a$, as follows :—

$$\begin{array}{lcl}
A & \qquad & A \\
4Aa + B & & 5Aa + B = \phi_4 a \\
10Aa^2 + 4Ba + C = \phi_3 a & &
\end{array}$$

In numerical application the operations may be made to stand thus, where a new letter below a line stands for the sum of the two preceding; and ϕa, $\phi' a$, &c., are introduced when found.

$$\begin{array}{cccccc}
A & B & C & D & E & F \\
 & Aa & Pa & Qa & Ra & Sa \\
\cline{2-6}
 & P & Q & R & S & \phi a \\
 & Aa & Ta & Ua & Va & \\
\cline{2-5}
 & T & U & V & \phi' a & \\
 & Aa & Wa & Xa & & \\
\cline{2-4}
 & W & X & \phi_2 a & & \\
 & Aa & Ya & & & \\
\cline{2-3}
 & Y & \phi_3 a & & & \\
 & Aa & & & & \\
\cline{2-2}
A & \phi_4 a & \phi_3 a & \phi_2 a & \phi' a & \phi a
\end{array}$$

If a be of only one significant figure (as 200, 6, ·03), all the operations necessary to fill up this process can be performed in the head, and we have thus (for the method is general, though our example be only of the fifth degree) a working method of answering the following question :—Given a certain equation $\phi x=0$; required the equation $\psi x=0$, the roots of which are each less by a than those of $\phi x=0$.

If ϕa came out $=0$, we should then know that a is a root of the equation: and the method of approximating to a root is as follows :—Suppose we have an equation of which the root (unknown to us) is 26·73. By trial, or otherwise, suppose we find that 20 is the highest denomination of the root, and we thereupon find another equation, each of whose roots is less by 20 than a root of the given equation: this is done by the preceding process, and one of the new roots (but unknown) is 6·73. If we can find that the highest denomination of this root is 6, we make another reduction of all the roots, and find a new equation, one of whose roots is ·73. If we can then find ·7 to be the highest denomination, we repeat the process and find an equation one of whose roots is ·03. In finding the highest denomination of this root we find the root itself, evidenced by the ϕa of this final process being $=0$.

The first denomination of the root must be found by trial, or by some of the methods referred to in THEORY OF EQUATIONS. But the second and the remaining ones are found by comparing the results ϕa and $\phi' a$. If a be nearly a root,

$$a - \frac{\phi a}{\phi' a} \text{ or } a + \frac{-\phi a}{\phi' a}$$

is still nearer. Consequently, by dividing $-\phi a$ by $\phi' a$, we may, after the second process, be sure of finding one figure of the remaining root correct. But after the first process we may be liable to an error of a unit (to be corrected by a new trial), as in extraction of the square root.

In order to obtain $-\phi a$ and not ϕa, let the last coefficient, F, have its sign changed, and let the process in the column which contains it be always subtraction, and not addition. In the preceding type of calculation, we should then have

$$\begin{array}{rcl}
-F & & F \\
Sa & \text{instead of} & Sa \\
\cline{1-1}\cline{3-3}
\text{Subtr.}\ -\phi a & & \phi a\ \text{Add.}
\end{array}$$

In carrying on the process, the results ϕa, $\phi' a$, &c., come in a diagonal line; before taking the next step, the beginner may bring them down into one line, as in the type preceding. In our examples, asterisks or other symbols will mark results of a process.

We now apply this method to the solution of the equation—

$$x^4 + 2x^3 - x^2 - x - 631064798 = 0.$$

It will be found that a root lies between 100 and 200.

---

[*] Mr. W. G. Horner was a schoolmaster and mathematical teacher residing at Bath, and died September 29, 1837. There has been some dispute about the right to the invention, of which we shall presently speak.

1	2	−1	−1	631064798(158

	610			

Assuming 100 as a first approximation, we find that $x^4+402x^3+60599x^2+4059799x-529074898=0$ is an equation having roots less by 100 than those of the given equation. And 529074898 contains 4059799 upwards of 130 times; but if any number of tens greater than 50 be taken, the accumulations of the next involution will give more than 5290, &c., as must be found by trial. Repeating the process, we find that $x^4+602x^3+135899x^2+13634699x-118087448=0$ is an equation all whose roots are less by 50 than those of the last. We can now depend upon 118087448 divided by 13634699 giving one figure of the root, and the quotient is between 8 and 9. Assuming 8, the first step of the third process shows that 8 is a root of the last equation, and 58 of the preceding, and 158 of the given equation.

We now give an example in which approximation is carried on. Let the equation be $x^3-6x^2+7x+4=0$, of which one root lies between 2 and 3.

		0·000248	8
		−4·485316‖	2

The root of this equation is found to be 2·414213562, as follows. Beginning with the multiplier 2, one set of involutions brings us to the figures followed by colons, and $x^3+0x^2-5x+2=0$ is an equation on which the process is to be repeated. Dividing −2 by −5 we find that ·4 is most probably the next figure, which is verified in the next trial, since the result of involution, 1·936, is less than 2. We proceed in this way until 2·4142, containing half the number of figures wanted, is found, and this being a, we have found −0·000060831 for $-\phi a$, and −4·485316 for $\phi' a$. The first divided by the second may be depended upon for doubling the number of figures, as commonly practised in the extraction of the square root. [APPROXIMATION.] The figures 13562 are found by a contracted division shown in the example.

But it is more convenient to avoid decimals in the process, which may be done as follows. 1. If there be decimals in the coefficients of the equation, annex ciphers to every place in such manner that the number of decimals in the several places may be in increasing arithmetical progression. Then strike out the decimal points entirely, and proceed as with whole numbers, remembering that the root thus obtained will be 10 times too great if the progression increase by units, 100 times too great if it increase by twos, and so on. Thus $1{\cdot}81x^3-{\cdot}6x^2+33x+18{\cdot}4$ should be changed into $1{\cdot}81x^3-{\cdot}600x^2+33{\cdot}0000x+18{\cdot}40000$, and $181x^3-600x^2+330000x+1840000$ will give ten times the required root. 2. When all the whole figures of the root have been obtained, and the decimal part is about to enter the calculation, before attempting to obtain the first decimal figure annex a cipher to the first working column on the left, two ciphers to the second, and so on to the end. Then proceed with the new figure as if it were a whole number, and make a new involution. When this is finished annex ciphers again as before. One additional advantage will be that the ciphers will serve to mark the places of completion of the individual involutions. If in any case ϕa should not contain $\phi' a$, place a cipher in the root, annex ciphers again, and then proceed. In some of the older algebraists, Oughtred for instance, the several vertical lines of figures are kept in their places by a set of ruled columns, the use of which is difficult. Mr. Horner has a similar contrivance; but the employment of ciphers removes all the difficulty, as in common division and the extraction of the square root. See the last example in this article. The method might easily be extended to the whole part of the root. The following is an instance of the method:—

$$x^4+x^3-x^2-2x-2=0$$

1	−1	−2	2(1·414,2136
2	2	1	−1
3	1	−1	30000

Many of the preceding figures are useless, but we have judged it best to present the whole process. The best method of abbreviation is to fix a point of the process from and after which the number of figures in the last column is not to increase, striking off at every step one figure from the last column but one, two from the last but two, and so on. The consequence will be, that the several columns on the right will disappear one after the other; the process will be legitimately reduced to termination with a contracted division, independently of the theorem cited; and the result will be true to the last place. The effect of this will be, that as soon as the remaining part of the root is too small for its highest power to show itself in the process, an equation of the $(n-1)$th degree takes the place of the nth, and so on, until there remains only an equation of the first degree, and the approximation then proceeds by the Newtonian method. All this was pointed out by Mr. Horner, whose view of his own method was very complete, in everything but historical information. Had he given in his paper an example from Oughtred, also worked by his own method, pointing out the difference of the two, we feel sure that the question about the right to the invention never would have been discussed.

Taking up the preceding example at the point with which we left off (neglecting the division), and following the process, we have

(Root obtained 1·414) 213562373

The answer 1·414213562373 is correct to the last place inclusive. (The contracted division follows the thick line.) The rule by which to judge of the extent to which the full process should be continued is as follows: Carry it on until the last column but one has at least two more figures than the number of root figures *remaining* to be found.

Such is the method which must place its author among those valuable inventors who find out simple adaptations which have been overlooked by their predecessors. It is not a little remarkable that this, the most important facilitation which the solution of numerical equations has received since the time of Vieta, and which is, *when known*, a very obvious extension of the extraction of roots, should have only preceded by a few years the most important addition to the method of ascertaining the number of roots which has been made since Des Cartes, and which is also, when known, an equally simple result of the process of finding the highest common factor of two algebraical expressions. [STURM'S THEOREM.]

Two of the most remarkable applications of this method are the solution of equations of the second degree, which is made as simple as the extraction of the square root, and the extraction of the cube root, which is reduced from an impracticably complicated process to one of perfectly easy performance.

As an example of the first, required the solution of

$$2x^2+x=2.$$

Since the root is less than unity, the preparation for decimals is made at the outset.

or $x=·78077643$, which is correct with the exception of the last place. The extraction of the square root, say of 10, is done by solving the equation $x^2+0x=10$; but it will be found that the solution of any equation of the form $x^2+ax=b$ may be performed by the same rule as the extraction of the square root. We shall show this, beginning with Horner's rule, and changing to the other after a few steps. Let the equation be $x^2+2x=10$.

In the extraction of roots, the method of pointing and bringing down the periods as they are wanted may be followed. The following is the process for the extraction of the cube root of 205692449327; it being remembered that the question is the solution of an equation of the form $x^3+0x^2+0x=a$:—

```
1    0       0            205692449327(5903
     5       25           125
     10      7500          80692
     150     1431          80379
     159     8931            313449327
     168     1512            313449327
     17700   104430000               0
     17703       58109
             104483109
```

The following process is the extraction of the cube root of 1·808, and will serve as an example of the complete process, omitting only the first column, which, with the exception of the unit at the head, is blank. And this is also the type of the solution of any cubic equation whatsoever; the only difference being that the heads of the first and second working columns are ciphers in the extraction of the simple root, and significant in all other cases.

```

The preparation for decimals makes the answer ten times too great; so that the cube root of 1·808 is 1·218...002, of which only the last figure 2 cannot be depended upon. The preceding contains every figure which need be written down, all the connecting operations being those which are usually performed mentally, and one only is required for each figure.

The vertical lines in the example show that part of the operation in which the contraction takes place, and the point at which the contraction becomes simple contracted division is marked by a thick horizontal line.

To enable the beginner to examine the process, we have placed a letter in every line of the first working column, by which the parts of the second column which are connected with it may be traced; while a letter doubled in the second column shows a multiplicand the product of which by the root figure is found as marked in the third column. The letters under the last line of the first column mark the figures cut off in the several contractions, and their results in the other columns are traced in the same way: the same for the letters under the second column.

One simplification might be made after the learner has practised a number of examples conducted as above. In the second working column, certain lines—namely, the second *b*, the second *c*, the second *h*, &c.—are not used except to be added to the next line. Hence, each of the lines on which a letter is doubled might be formed by adding the first, third, and fourth preceding lines, and the effect would be to omit some of the lines and some of the most simple additions. The second column, beginning from *pp* inclusive, is a specimen, and changing the line in which ciphers are annexed (and the ciphers should always be annexed to mark the step) would be—

44521433589	*pp*
109639800	*q*
32892291	*s*
4452285890991	*ss*
32892372	*t*
292377	*v*
445232170713	*vv*
292377	*v*
2192	*w*
44523248501	*ww*

But considering that the process is one which no person will very often perform, we doubt whether to recommend even this abridgment. All such simplifications tend to make the computer lose sight of the uniformity of method which runs through the whole; and we have always found them, in rules which only occur now and then, afford greater assistance in forgetting the method than in abbreviating it. But one abbreviation, when duly learnt, is found to have very great advantage. The addition of the products which are carried from each column to the next—and for the last column, the subtraction—might be made at once, figure by figure, as fast as the figures are formed.

On evolution of algebraical quantities we do not think it necessary to speak, since either the binomial theorem [BINOMIAL THEOREM], or some other method of development, is employed with more advantage than the usual modification of the arithmetical process. We have also omitted the process of division, the most simple of all evolutions, since its connection with the preceding is sufficiently obvious.

There is, however, a process of an evolutionary character which we take this opportunity of suggesting, and of which any one moderately conversant with algebra will easily arrive at the demonstration. In finding the highest common divisor of two algebraical integral expressions, and also in the process of Sturm's theorem, it is required to divide one expression, P, by another, Q, not for the sake of finding the quotient, but the remainder; and this remainder, cleared of all numerical factors and of fractions, is preferable. The following rule will render the application of Sturm's theorem much more easy:—

Question:—Two expressions, P and Q, being given, of which P is lower than Q, required the remainder of Q divided by P, cleared of fractions and of positive numerical factors. To take an example with us, let

$$P=2x^3-x-4$$
$$Q=4x^5-3x^4+2x^2-x+1.$$

1. Add 1 to the difference of the degrees $(5-3=2,\ 2+1=3)$: this is the number of operations to be expected. In this case it is three.

2. Write down in two lines the coefficients of the divisor and dividend, including the coefficient 0 for every missing term, but change the sign of every coefficient in the divisor, *except the first*. Clear both expressions of all whole factors; and if the two leading coefficients (2 and 4) have a common factor, divide by this factor before writing them down. Write ciphers in all blank places.

(P)	1	0	1	4	0	0
(Q)	2	−3	0	2	−1	1

3. Take the first vertical pair, and every other in succession, and make cross multiplication and addition: thus, $\begin{matrix} a & \cdot & \cdot & \cdot & c \\ b & \cdot & \cdot & \cdot & d \end{matrix}$ gives $ad+bc$. Put the first result in the first column, the second in the second, and so on.

(1)	−3	2	10	−1	1

4. Repeat this process with the first line, and the result just obtained, and again with the result, making each new result out of the first line and the last result, and so on till the number of operations ascertained in the first clause of the rule has been performed. But if the leading term of the first line have been divided, multiply that leading term again after the result, unless the first term of the result be also divisible by the same factor.

5. But if ever the first column of a result should turn out a cipher, throw it away, and bring forward the next column, and so on, making every step stand in the next higher place; and if the two first columns of any result should be ciphers, throw them away, and bring forward the third, and so on. And for every cipher thus thrown away, diminish by one the number of operations required in the first clause.

6. If any horizontal line thus obtained have a factor in all its terms, divide by that factor, taken positively, before proceeding further; and if the leading term of any new result have a factor in common with the leading term of the first line, divide both before proceeding.

The table of results now is as follows, in which the various changes of the leading terms are shown by putting them down as they occur, and putting a bar over them as they disappear and are replaced by others. In practice, the pen may be drawn through the figure which is dismissed.

(P)	$\bar{2}$, $\bar{1}$, $\bar{2}$, 1	0	1	4	0	0
(Q)	$\bar{4}$, 2	− 3	0	2	− 1	1
(1)	−3	2	10	− 1	1	
(2)	$\bar{4}$, 2	17	− 14	2		
(3)	17	− 12	10			

$17x^2-12x+10$ Answer.

7. When the last result has been obtained, make an algebraical expression one degree lower than the divisor, the coefficients of which are the numbers in the last result, with their signs.

The real remainder in the preceding example is $8\frac{1}{4}x^2-6x+5$.

Let the next example be

$$P=4x^3-6x^2+x+1$$
$$Q=2x^6-3x^5+2x^4+x^5-3x^3-3x+4.$$

Here the number of operations should be four; but it is reduced by the circumstance mentioned in the fourth clause of the rule.

(P)	$\bar{4}$, $\bar{2}$, $\bar{4}$, 2	6	− 1	− 1	0	0	0
(Q)	$\bar{2}$, 1	− 3	2	1	− 3	− 3	4
(1)	$\bar{0}$,* 3	1	− 6	− 6	8		
(2)	$\overline{22}$, 11	− 27	− 27	32			
(3)	12	− 65	53				

$12x^2-65x+53$ Answer.

The method of verifying the several processes, as their results arise, is as follows: Make an additional proof column, in which place the sums of the numbers in each line, taken with their signs; making these sums vary with the variation of the leading factors: thus

			Proof.
a	*b*	*c*	A
p	*q*	*r*	P
aq+*bp*	*ar*+*cp*	. . . . . .	Z

Here A is $a+b+c+\ldots$; P is $p+q+r+\ldots$; and Z is $aq+bp+ar+cp+\ldots$. If then the process be correctly done, an extension of it to the proof column gives $aP+Ap$, which ought to exceed Z by $2\,ap$.

We shall conclude this article with the process which will be applied hereafter. [STURM'S THEOREM.] The object is to proceed as in finding the greatest common divisor of P and Q, changing the sign of every remainder before using it.

$$P = 4x^3-9x^2-4x+1$$
$$Q = x^4-3x^3-2x^2+x-3$$

					Proof column.
4	9	4	− 1	0	16
1	− 3	− 2	1	− 3	− 6
− 3	− 4	3	− 12		− 16
− 43	0	− 45			− 88
43	0	− 45	0		− 2
4	− 9	− 4	1		− 8
− 387	− 352	48			− 696
− 15136	19264				4128
15136	19264				34400
43	0	45			

The remainders therefore, with the signs changed as directed, are $43x^2+45$, $15136x-19264$, and the last is a negative whole number. The following is the first instance of the use of the proof column:—

$$1\times 16+4\times(-6)-(-16)=8=2\,(4\times 1)$$

In the preceding part of this article we gave an account, with instances, of the method of solving equations, which is commonly known by the name of the late Mr. W. G. Horner, schoolmaster, of Bath. We believe we may usefully give what precedes a considerable extension: first, because the method [COMPUTATION] is one of the best exercises in computation; secondly, because neither its meaning nor its history is very generally understood, and the latter is very instructive.

The process of *involution* as above defined, is the formation of the value of a rational and integral algebraical expression, such as ax^3+bx^2+cx+d, by a succession of multiplications separated by additions, as in

$$\left\{(ax+b)x+c\right\}x+d.$$

Horner's mode of doing this takes the figures from left to right, or takes those of largest value first; and exhibits a plan of performing the operation which combines the result of each figure with the joint result of all that come before. Thus in finding the value of the preceding when $x=123{\cdot}456$ the value is first found when $x=100$; then, by help of the preceding, when $x=120$; then when $x=123$; then when $x=123{\cdot}4$; and so on. By this means we are enabled to proceed, when the value of the succeeding figures depends upon the results of those already found, as happens in all the cases of *evolution*, the inverse process. To take, however, the direct process first, we shall exhibit at length the finding of $9x^3-3{\cdot}141x^2+{\cdot}009x-1427{\cdot}499$, when $x=121{\cdot}23$; or, to avoid decimals in the expression, we may consider this as the thousandth part of $9000x^3-3141x^2+9x-1427499$. The process is as follows: a great many figures (about 115) being repeated twice over, in a manner wholly unnecessary in computation, in order to facilitate the explanation.

---

* Then bring forward the next column.

9000,	− 31,41	,0009	− 1,427499(121·23
	8968,59	8968,5909	8967,163401

	326925900		
	326952900		
	326979900		
	328006900		
	———		

We first put down the coefficients as usual, not changing the sign of the last (which is only a convenience for *evolution*, and does not alter any figure). The value of x being 121·23, we begin with 100, which, having two ciphers, we mark off by commas from the several coefficients 0, 2, 4, 6 places. We then proceed by Horner's process with the figure 1 (not 100), taking care to make commas fall under commas, or to use the commas as if they were decimal points (which they are in fact, though not *unit-points*). As soon as we have done the first process, containing all that comes before the lines A, we learn as follows. Let

$$\phi x = 9x^3 - 3{\cdot}141x^2 + {\cdot}009x - 1427{\cdot}499$$

then, x being 100, ϕx, $\phi' x$, $\frac{1}{2}\phi'' x$, and $\frac{1}{6}\phi''' x$ are severally 8967163·401, 269371·809, 2696·859, and 9. We then write down the results again, after the lines A (which is not necessary in calculation), merely to show the new disposition of the commas. We are now to proceed with 20 (from the first 2 in 121·23), which, having one cipher, we mark off 0, 1, 2, 3 places in the several columns. Immediately before the lines B we learn that when $x = 120$, ϕx, $\phi' x$, and $\frac{1}{2}\phi'' x$ are severally 15505343·181, 388046·169, and 3236·859. We then write down these results without any commas, and proceed with the second 1 in 121, from which we find that when $x = 121$, the functions are 15896635·209, 394546·887, and 3263·859. We then begin to provide for the decimal point, by annexing one, two, and three ciphers to the working columns, and taking the second 2 in 121·23 to work with, and applying Horner's process, we find, when $x = 121{\cdot}2$, that ϕx, $\phi' x$, and $\frac{1}{2}\phi'' x$, are severally (remembering that all the annexed ciphers are so many additional decimal places) 15975675·212760, 395853·51060, and 3269·2590. Finally, we annex the ciphers again, and with the 3 we find that $x = 121{\cdot}23$ gives 15987553·760654100, 396049·6904400, and 3280·06900.

Let us now compare the trouble of this process with that of any other method of doing the same. If we throw out all the figures which we have written twice over merely for explanation, and also the last two and one lines in the second and third columns, which are only wanted to go on further with, we have written down about 280 figures. The ordinary verification costs about 340 figures. It is true that every step is both a multiplication and an addition in one: but this can be done and ought to be done in the use of this method, and is not done in the ordinary method. And we have not only the advantage of a purely mechanical method, in which the first arrangement causes the succeeding steps to require nothing except a look at the successive figures of the value, but the still greater advantage of being able, at the end of the process, to make any small alteration of value with ease. If, for instance, having discovered that 121·297 would do better than 121·23, we wish to get additional accuracy, we have but to rub out the last 3 process, and proceed with 9 and 7. In the ordinary mode, we must either repeat the whole process again, or correct approximately by substituting 121·23—·003, which will require us to calculate $\phi' x$, and perhaps $\frac{1}{2}\phi'' x$.

We shall now exhibit a common multiplication, and the formation of a square; not, of course, that we attach any particular value to these simple cases, but that we may show the uniformity of the process. Required 14796 × 32316, or the value of $14796x + 0$ when $x = 32316$. We repeat the lines as before, which is more than is necessary, and makes this process look very long.

	55892	

The process here described is one which, we venture to say positively, has neither been put in its right place, nor received its due reward. It is the natural extension of the common process of multiplication, and its inversion is as naturally and necessarily the proper mode of solving equations, as the inversion of multiplication is the same for the simple equation $ax=b$, or common division. The inventor of it must rank, not with the analyst or the algebraist, commonly so called, but with the discoverer of the process of multiplication and division, and the extraction of the square root.

The application of this method to the solution of $\phi x = 0$ consists in finding the first figure by trial, and making use of the Newtonian approximation to find successive figures: namely, that if a be nearly a value of x, $a - \phi a : \phi' a$ is more nearly so. This method becomes difficult when two roots are nearly equal; but the difficulty lies in what may be called Newton's part of the complete method, not in Horner's part. When the difficulty of algebra shall be conquered, the process of arithmetic may easily be amended in the *trial part*; but to suppose that a capital improvement in the manner of conducting computations is little worth, because it is not accompanied by a victory over difficulties of quite another kind, is unreasonable. With a little more trial, Horner's method may be applied to the case of nearly equal roots; and as it is, it is more efficacious in discovering them than any other method.

To what has been said upon the method, we may add the following remarks:—1. When the last term is positive, and would in the ordinary process be made negative, it is often better, instead of changing the sign of the last coefficient only, to change the sign of all but the last. Thus in solving $x^3-11x+1=0$, the heads of the columns, should be − 1, 0, 11, and 1, instead of 1, 0, − 11, and − 1. Also, that if at any period of the process the divisor and dividend columns should become negative, the signs of all should be immediately changed.

2. In making the contractions, it will be advisable to make the figure which comes next after the separating line correct, to continue it, in fact, till the next contraction, and to use it to carry from. This is not done in what precedes, but it is done in the instance in COMPUTATION. In that instance, the following figures, seen one over the other in the last column but one, as follows, 3, 5, 7, − 6, 9, 1, − 2, 2, 2, are figures cut off by the contraction, but made up from the second column to carry from into the fourth.

3. If, at the beginning of the process, all the heads of the columns be multiplied by 9, the root will not be altered, and, until the contraction begins, the verification by casting out nines is rendered easy, since every result in every column is divisible by 9.

We shall now show how the process works in some equations which have equal, and nearly equal, roots.

Let $x^4-6x^2+9=0$, which has two roots, each equal to $\sqrt{3}$.

−1	0	6	0	9 (1·7320
	−1	5	5	40000
	−2	3	8000	1210000
	−3	000	5697	5041
	−40	−329	748000	3
	−47	−707	401653	
	−54	−113400	49132	
	−61	−115449	25190	
	−680	−117507	1220	
	−683	−119574		
	−686	−11971		
	−689	−11985		
	−692	−11999		

The existence of equal roots, or of nearly equal roots, might be here suspected from the slow increase of the divisor column; but the method cannot verify the fact of their being two absolutely equal roots. The column preceding the divisor column being large and negative, requires us to make trial of figures above, not below, those which the divisor column seems to indicate. But nearly equal roots may sometimes be detected, as in the following instance. Let $7x^3-10x^2-14x+20=0$, of which it is known that one root lies between 1 and 2. The ordinary process gives

−7	10	14	20 (1·41421356
	3	17	3000
	−4	1300	8000
	−110	748	1547000
	−138	8400	61608
	−166	6453	3859
	−1940	449900	1013
	−1947	371348	160
	−1954	292684	18
	−19610	288745	1
	−19638	284806	
	−19666	28460	
	−19694	28440	

This root may be carried on without difficulty. But at the end of the second process, when the dividend is reduced to 8000, the divisor only 8400, and the preceding column as much as −1940, it may be worth while to try another figure. This state of things gives a suspicion that there is another root in the immediate vicinity of the one in hand. If the three last columns be $+a, b$, and c, and if we find that $pa+b$ is nearly $c\div p$, which is the trial test of p being a new figure of the root, we are sure that $(p+1)\ a+b$ will not be near $c\div(p+1)$: and moreover $p\ (pa+b)=c$ has not two positive roots. But if the three last columns be $-a, b$, and c, it may very easily happen that $b-pa$ may be nearly $c\div p$, and $b-qa$ nearly $c\div q$; for $p\ (b-pa)=c$ has two positive roots. Perfect certainty, in the absence of an easy algebraical criterion, may only be attainable by trying every figure. In the instance before us, finding 1·41 succeed, with a presumption of a larger root, we try 1·43, beginning with

−7	−1940	8400	8000
	−1961	2517	449
	−1982	−3429	
	−2003		

This figure will not do, for now a permanent difference of sign is established between the dividend and divisor columns. We then try 2, as follows:—

−7	−1940	8400	8000
	−1954	4492	−984
	−1968	556	
	−1982		

There is now a difference of sign between the two last columns, but, looking at the second column, we see that agreement may be restored by the next figure. The figure 8 will do it, as follows:—

−7	−19820	55600	−984000
	−19876	−103408	−156736
	−19932	−262864	
	−19988		

and 26286400 is not contained 10 times in 156736000. All the signs being now negative, we may change them all. If we had tried 7 instead of 8, we should have had

−7	−19820	55600	−984000
	−19869	−83483	−399619
	−19918	−222909	
	−19967		

But now 22290900 is contained more than 10 times in 399619000, which shows that 7 is not high enough. If we try 9, we have

−7	−19820	55600	−984000
	−19883	−123347	+126123

and a permanent difference of sign is established between the two last columns, whence 9 is too high. Proceed then with

·7	199880	26286400	156736000	(1·428

and we find 1·42857142857 ... for a root. The reader may watch the operation in the following equation:

$$(9\,x-10)\,(9\,x-11)\,(30\,x-37)=0,$$
$$\text{or } 2430x^3-8667x^2+10293x-4070=0$$

the roots of which are 1·111 ..., 1·222 ..., and 1·233 ...

Whatever common figures two roots of $\phi x=0$ may have begun with, there must be a root of $\phi'.x=0$ which begins with these figures. And whatever common figures three roots may begin with, there must be two roots of $\phi'x=0$, and one root of $\phi''x=0$ which begin with those figures: and so on. If there were a difficult equation having three roots nearly equal, no method of detecting them would be easier, of all those known at present, than solving contemporaneously the three equations $\phi x=0$, $\phi'x=0$, $\phi''x=0$, not making any step in one till all had been brought up; that is, one step of each first, then the second of each, and so on.

It may happen that a finite root is established, and yet that the process must be continued to obtain another root beginning with the same figures. For example,

$$9x^3-46x^2+75x-38=0$$

It will be seen in the following process that 2 is a root, with a presumption, from the appearance of the divisor column and the one before it, that there is another root beginning with 2. And by trial 2·1111 ... is found to succeed.

9	−46	75	38 (2·11111
	−28	19	0
	−10	−100	11000
	80	−11	1221
	89	8700	23
	98	9779	12
	1070	10867	1
	1079	10977	
	1088	11087	
	1097		

We shall now proceed to a short account of the history of this problem, and of the controversies which have existed, and to some extent still exist. For a fuller account of it up to the time of Mr. Horner, see a paper by the writer of this article in the 'Companion to the Almanac,' for 1839.

Before the time of Vieta, evolution consisted in the rules for the performance of division, and extraction of the square and cube roots, in forms probably derived from the East. To him [VIETA, in BIOG. DIV.] we owe the first publication of a numerical method of finding the successive figures of the root of an algebraical equation by means of the value of the function equated to zero in the equation. This method of Vieta is in fact that which Horner's process now makes so easily practicable. If $\phi x=0$ be the equation, and a a part of the root, it uses ϕa, and $\phi\,(a+1)-\phi a$ as a divisor. The process is so cumbersome, that Vieta does not attempt to apply it to equations having more than two figures in the root.

This method attracted but little attention on the continent: but in England, where everything relating to numerical calculation has been always diligently studied, it was much noticed, and received extensions of power. In the posthumous work (1631) of Harriot [HARRIOT, in BIOG. DIV.] examples of it are given with the improvement of forming only so many figures of the divisor as are wanted: and he ventures upon roots of three places. In the second edition of Oughtred's 'Clavis Mathematica' (1647) Vieta's method is given without Harriot's improvements. But the first who used Vieta's method to any great extent was Briggs, in the calculation of the sines, &c., in the 'Trigonometria Britannica.' In the preface the method is applied to equations of the third and fifth degrees, and partially described for the seventh and higher degrees: with examples carried to fifteen and sixteen figures of the root. It is for the facilitation of these solutions that the Abacus παγχρηστος is given, which some have unreasonably interpreted as giving Briggs a claim on the binomial theorem. Gellibrand tells us that Briggs formed his tables of sines by algebraic equations and differences about thirty years before his death. Now Briggs died in 1630, and Vieta's tract appeared in 1600: the former must then have received the work soon, immediately seen the importance of the method, and commenced operations by means of it. We cannot give Briggs any independent title to the invention; for it is likely enough that he was in correspondence with Vieta, whose works he certainly knew. One of his examples is the solution of what would now be written

$$x^3-3x=1{\cdot}298896096660366$$

for which he gets $x=1{\cdot}917639469736386$. He puts down the work as far as ... 697, proceeding towards the end by several figures at a time: and he has got what Vieta had not, the Newtonian divisor $\phi'x$ instead of $\phi(x+1)-\phi x$. Of course it adds materially to the historical value of this method that it was thus used in an operation of so much importance to the progress of mathematics in general. The dates above given may even cause a suspicion that it was the power of solving equations thus suddenly acquired, which first suggested the calculation of the natural sines, &c., in the 'Trigonometria Britannica.'

Wallis, in his Algebra (1684), gives the method of the "*numerose exegesis*," as he calls it (Vieta had called it *potestatum adfectarum ad exegesin resolutio*) with an example of the fourth degree worked to seventeen places of the root. He makes use of the method of contracting the figures towards the end. In this same Algebra appeared, for the first time, what is called Newton's method of approximation, which soon superseded the exegesis, into which however it had been virtually incorporated by Briggs. Newton's approximation, at least in the general form which it took in the hands of Taylor, is as follows. If a be a near value of x in $\phi x=0$, then, except when there are two nearly equal roots, a nearer value is

$$a-\frac{\phi a}{\phi' a}\text{ or }a+\frac{-\phi a}{\phi' a}$$

The old exegesis, and especially Briggs's form of it, employs this principle: — ϕa is calculated, and either $\phi' a$ or $\phi(a + 1) - \phi a$. Briggs, who proceeds by several figures at a time, and uses $\phi' a$, does really use what was afterwards called Newton's method, and assists it by operations suggested by Vieta.

When the exegesis was abandoned by Raphson and others, in favour of Newton's form of operation, no further improvement was made in the direct numerical solution of equations, until the time of Mr. Horner; at least no further improvement was published. Mr. Henry Atkinson, a young man of Newcastle, re-invented the whole method in 1801, applying Newton's divisor, and giving rules by which one divisor was made to help in forming the next. This was read to the Philosophical Society of Newcastle in 1809, and published posthumously, as 'A new Method of extracting the Roots of Equations,' Newcastle, 1831, 4to. In our article in the 'Companion to the Almanac, already cited, we have supposed that no one can be shown either to have used $\phi' a$, or to have made each value of it help the next, before Mr. Atkinson: but we now find that Briggs was before him in both points.

Lagrange's method of transforming the root into a continued fraction [THEORY OF EQUATIONS] does not need notice here, because it belongs to another mode of expression. But it ought to be noticed that Horner's process very much abridges the labour of Lagrange's method, as much indeed as it does that of Vieta's exegesis, and for the same reason. Mr. Exley, of Bristol, in the 'Imperial Encyclopædia,' article ARITHMETIC, improved (according to Horner himself) the common method of extracting the cube root, so as to precede Horner in this particular case. We believe more than one method had been given for reducing the enormous labour of the ordinary extraction of the cube root: we may mention one, which is ingenious and effective, and almost exactly a particular case of Horner's method, given by Mr. A. Ingram, in his edition of Hutton's 'Arithmetic,' Hawick, 1811, 8vo.: and Horner himself refers to an edition of Melrose's 'Arithmetic,' by Mr. Ingram (the same, we suppose) as containing such a method.

Horner's paper was read to the Royal Society on the 1st of July, 1819, and was published in the current volume of the Transactions, on the 1st of December. These dates are of importance: the publication of the above paper was the signal for more than one person to make a nibbling claim to the invention. Horner was unfortunate in two points. First, he had not sufficient knowledge of ancient algebra to be aware that his method contained the process of Vieta, and that his real claim consisted in the discovery of the beautiful process by which the labour is immensely reduced, and completely systematised: we suspect that he completely re-invented Vieta's part for himself. Secondly, he appears to desire to be the analyst rather than the arithmetician, and will not show anything except to those who can take all. It is true, beyond a doubt, that his method is adapted to every sort of equation, and that it is as great a help to the person who desires to solve $\tan x - ax = 0$, or $\epsilon^{\sin x} = x$, as to the other who wants nothing but a common algebraical equation. So far, then, it is more than Vieta's method simplified; it is the same also extended. But if the inventor had proceeded from simple algebra to the more complicated cases, his merits would have been more rapidly appreciated. He did not well see that his mode of solution applies as well to the integer part of the root as to the fractional; nor did he fully comprehend how much of his own discovery consisted in the general mode of calculating the value of ϕx, as given at the beginning of this article. But that we may not do him injustice, and still more that we may enable those of our readers who have not access to the original paper to see how completely he had got hold even of the most convenient arithmetical process, we give his solution of the famous Newtonian instance $x^3 - 2x = 5$. After reducing the root by 2, the heads of his columns are 1, 6, 10, and 1 (the first column, which is always vacant, he does not set down). He then annexes either dots or ciphers, and proceeds exactly as follows

When Mr. Horner's paper had been published six months appeared 'A new Method of Solving Equations,' by Theophilus Holdred, London, 1820 (preface dated June 1), 4to. The method is taken from Harriot; and a supplement is added, which gives Horner's method. Both are claimed as independent inventions, and Horner's name is not mentioned. Mr. Holdred asserts that, after having had his method for forty years he was led to that in the supplement * by a mistake he committed in solving an equation sent him by one of his subscribers. We have given, in the article of the 'Companion to the Almanac,' already cited, our reasons for coming to the conclusion that Mr. Holdred took his first method from Harriot, and his second from Horner.

A claim was made by Mr Peter Nicholson in various places, which is quite futile. We acquit Mr. Nicholson (a highly respectable man, eminent in the application of mathematics to the arts) of all unfair intention: and we must remind our readers of a point without the knowledge of which the various controversial writings on this subject will be full of confusion. Hardly any one knew of Vieta's Exegesis, which there is little doubt that both Horner and Atkinson reinvented. In fact, so completely had this exegesis dropped out of sight, that even Dr. Peacock, in his short account of Horner's method ('Report on Analysis to the British Association') does not allude to it. Accordingly, all the re-inventors of Vieta's method speak of quite new rules discovered for the solution of equations, and treat Horner's process as a constituent part of one of the new inventions. But a person acquainted with the history of the subject finds nothing new except Horner's process. Vieta had the main system, Briggs had the Newtonian divisor, Wallis had the method of contraction, Briggs had *a* method of making one divisor help the rest: Horner had *the* method which must finally be adopted. Budan, as we shall see, had only a particular case of that method, and did not apply it to any mechanical process of numerical solution.

Mr. Nicholson claims Horner's identical process, and fairly refers to the very place in which he says it is to be found. But on looking there (see the article already cited in the 'Companion to the Almanac'), we find that he has been deceived by a distant resemblance, and that, though he has given a new and useful process for a useful purpose, neither the process nor the purpose is Horner's. At the same time it is but justice to Mr. Nicholson to say, that in his 'Elements of Algebra,' London, 1819,† 12mo, he made as near an approach to Horner's method as could well be done, and applied it in the case of equations of the second and third degrees. The succession of columns is seen, each column helps the next, and each step in any one column helps the next step. But the grand simplification, which the controversialists called the "non-figurate method," is wanting: so that this process of Nicholson's is perhaps hardly more than Briggs was in possession of. Mr. Nicholson had received Mr. Holdred's method, whose name he properly mentions in the preface. This method he had greatly improved; and it seems he wished that Holdred should publish his own method as amended by him; but he asserts (in the preface to his work on Involtion and Evolution) that the latter refused, alleging that his own credit would be diminished, unless he could pass them as his own.

Dr. Peacock had never seen Holdred's tract, and his result, derived from the assertions of Mr. Nicholson and from Horner's paper, is that Nicholson, by a combination of the methods of Holdred and Horner, reduced the method to its present practicable form. But any one who will solve $x^3 - 2x = 5$ in the systematic form we have given, will see that Horner had that form. Nicholson was, we believe, the one who first clearly saw that the method, in its simplest organisation, applies as well to the integer as to the fractional portion of a root. All Mr. Nicholson's simplifications, as given in his latest writings, consist in doing in the head some of the things which Horner put down on paper. The form we give carries this still further; and those who can do what we have recommended all arithmeticians to practise in COMPUTATION can follow us: but there is no invention in this.

Some have been disposed to give a good deal of the merit of this system to Budan; and his claim must be considered. Two editions of the 'Nouvelle Méthode pour la Résolution des Equations numériques,' Paris, 4to., were published in 1807 and 1822. The basis of M. Budan's operations is the simple case of Horner's process in which the root of an equation is diminished by unity. This is done exactly in the mode by which Horner afterwards proceeded. Thus to lessen the root of $x^3 - 2x - 5 = 0$ by unity, Budan proceeds thus:—

$$\begin{array}{rl} & 1+0-2-5 \\ & 1+1-1-6 \\ (\text{A}) & 1+2+1 \\ & 1+3 \\ & 1 \end{array}$$

$$\text{Answer } x^3 + 3x^2 + x - 6 = 0$$

But to lessen the root by 2, Budan is never able to arrive at the process on the left, which is Horner's: he must repeat the process of diminishing the last root by one, as on the right.

---

* We cannot but believe that Mr. Holdred did see Mr. Horner's paper. Had he mentioned it, and the name of the subscriber, his equation, the mistake made, &c. &c., distinctly declaring when and where he first saw Mr. Horner's paper, he might have possibly established a claim to be a second inventor.

† The preface is dated May 17, 1819, and the publication took place early in July, Mr. Horner's paper having been publicly read at the Royal Society on the first of that month.

	$1+0-2-5$	$1+3+1-6$	
	$1+2+2-1$	$1+4+5-1$	
(B)	$1+4+10$	$1+5+10$	(C)
	$1+6$	$1+6$	
	1	1	

Accordingly Budan has both (A) and (C) to do, where Horner has only (B). To diminish a root by 3, Budan has 3 processes, and so on. To diminish a root by 10, 20, &c., he divides the roots of the original equation by 10, then diminishes by 1, by 1 more, &c., and then multiplies the resulting roots by 10, 20, &c.; and similarly for 100, &c. It is obviously possible, by a large amount of calculation, to obtain the root of an equation in this manner; but Budan is not only obliged to call in other methods, and even thus to spend very great labour, but he ends by presenting the root in the form of a sum of common fractions, each of which must be reduced to a decimal. Thus for $x^3-2x=5$, he gets

$$x=2+\frac{1}{11}+\frac{1}{275}+\frac{1}{165925}=2{\cdot}094551481364$$

Budan's method is not then even of the same species [*] as Horner's. In an appendix added to the edition of 1822, two years after Horner's paper, there is the method extended to the process for diminishing the root by n (Horner's process), but no use is made of it, and singularly enough the only example given is one in which n is -1.

Horner ('Leybourn's Repository,' page 38, of part ii., vol. v.) denies ever having seen Budan's work until 1818, after his method was finished. This, in one point of view, counts for nothing; for every discoverer has a right to have it supposed that those who come after him have used his works: that is to say, the first discoverer would have a right to the credit therefrom arising, even though it could be shown that subsequent discoveries were made without his aid. If a partial or unfinished method turn out to have a value of quite a new character when made complete, it is impossible to deny to its author the credit of having been further than his contemporaries on the road towards the complete method: consequently, Budan must have, in one sense, the merit of having proposed a particular case of that which Horner afterwards used. But, as it happens, a contemporary of Mr. Horner, in trying to insinuate that Horner had taken his method from Budan, has furnished independent evidence to the contrary. Mr. Nicholson, in a note to the preface (page ix.) of his essay 'On Involution and Evolution' states: "I am informed by Mr. Dickson that about twelve months ago he (Horner) purchased at his shop, in St. Martin's-le-Grand, an 'Essay on the Numerical Solution of Equations,' by Budan; at which time he mentioned that he was engaged expressly on this subject." This called forth the preceding statement from Mr. Horner, who, had he any unfair intention, and had he really been indebted to Budan, would have argued from the date of Mr. Nicholson's preface that he must have bought Budan only just time enough to insert the note about him in his paper before he sent it to the Royal Society. Instead of this, he answers in the most straightforward manner, that he bought Budan about July, 1818, nearly *two* years before Mr. Nicholson wrote; but avers that his method was then finished. And this we entirely believe; and also that it would have been impossible for him, fully engaged as he was in teaching a school, to have produced his method, so as to send it to the Royal Society in the spring of 1819, if he had only seen the first hint in the summer of 1818. But had he seen Budan's work, and had he thence derived the hint which he improved, his merit would not have been the less: Lagrange, the greatest writer on equations then existing, had seen it; Legendre had seen it: and both had closely examined it, and reported to the Institute upon it. The members of the Institute had seen it. Lagrange, too, knew of Vieta's Exegesis. But no one, except the Bath schoolmaster, ever brought forward Budan's method, or any extension of it, either from Budan, or independently, to the improvement of Vieta. Fourier had seen Budan's book, and had invented a method of his own of solving equations; or rather had given his own mode of conducting Newton's approximation; but this method is far below that of Horner.

We have written so much on the discovery of this method, because unfair attempts were made by claimants who had no title whatever to deprive the author, who was a man of real genius, of his rights over his own discovery. We refer to MM. Holdred and Nicholson: though we do not believe the second was knowingly unfair. Mr. Atkinson, when he first saw the "non-figurate method" (as some called the subject of this paper), saw and said that it was a "capital improvement." We have written also because it can hardly yet be said that mathematicians are alive to the value of this grand completion of the system of arithmetic. The continental writers show no knowledge of it; the Oxford and Cambridge elementary works do not yet recognise its existence, except so far as this, that one very recent Cambridge edition makes an imperfect introduction of it. The fact is, that mathematicians dislike calculation, and are apt to form hasty opinions on numerical methods before they have given them sufficient trial. The first elementary writer who brought Horner's method into instruction was Mr. (afterwards Professor) Young, in his 'Elements of Algebra,' published in 1823.

In 1831, eleven years after this method was published, appeared Fourier's posthumous work on equations, containing an extended use of Newton's method. It amounts to employing ϕa, $\phi' a.h$, $\frac{1}{2}\phi'' a.h^2$, &c., to calculate the value of $\phi(a+h)$, and $\phi' a$, $\phi'' a.h$, &c., *separately*, to calculate $\phi'(a+h)$; and so on. Fourier was an expert arithmetician, and in this very work shows his power of suggesting new forms of arithmetical process; but he does not come near anything like making the previous calculation of $\phi^{(n)}(a+h)$ give assistance to that of $\phi^{(n-1)}(a+h)$. The equation $x^3-2x=5$, which Wallis happened to take as his instance of Newton's method, has always been the example on which numerical solvers have shown their power. No one can be said to have carried a method beyond those which preceded, unless he has solved this equation to more places than they have done. Fourier went to thirty-two decimal places, which we do not know that any one had done before. Some students of University College, London (and one of King's College), none exceeding eighteen years of age, carried Horner's process further still, their independent calculations giving root to 52 figures. Some years afterwards, another student of University College, Mr. W. H. Johnston, of Dundalk, carried the solution to 101 decimal places, and verified it by the independent solution of a related equation. In 1851, Mr. J. Power Hicks, of Lincoln College, Oxford, then a student of University College, carried the solution to 152 decimal places, never having seen Mr. Johnston's result, with which, so far as it went, his own agreed. This last solution[*] is as follows, and it took about 50 hours of calculation:—

2·09455,14815,42326,59148,23865,40579,
30296,38573,06105,62823,91803,04128,
52904,53121,89983,48366,71462,67281,
77715,77578,60839,52118,90629,63459,
84514,03984,20812,82370,08437,22349,
91

We insert this conclusion as a challenge to any who still hold the opinion, which as a matter of course was maintained by some when Horner's method first appeared, that some older methods were superior to it. There were those who thought that the method of trial and error, or of false position, as it was called, was preferable. Mr. Nicholson gives, as the work of a young computer, the following solution of

$$4x^6+7x^5+9x^4+6x^3+5x^2+3x=792$$

$$x=2{\cdot}05204,21768,79605,36521,40434,01281,20197,34602,75599,54554\ 17242,14$$

An able[†] calculator informs us, that he makes the figures after 197 to be 34660, 87786,99113,74218,13787,467.

We have left entirely out of sight all the irrelevant controversy relating to the method of finding the limits of the roots, conducting the process when two roots are nearly equal, and so on. The claims of Budan, Fourier, Horner, &c., are here mixed up in a manner which requires a sifting investigation. Very frequently the value of Horner's method is stated as depending upon points of this kind. When any of the doubtful cases arise, which we noticed at the beginning of this article, we find, for ourselves, that the ease with which repeated trials are made by Horner's process gives us more command of these questions than anything else; in fact Fourier's theorem [STURM'S THEOREM] is very easily brought to bear by means of it. But it must be admitted that all methods which in any way include the Newtonian approximation are imperfect, when roots are nearly equal, in not having a better addition to the root a already obtained than $-\phi a : \phi' a$. Let a better method come, and we have no doubt that Horner's process is more ready to make easy use of it than any other. A student who is very slow at finding out the trial figures of common division, might as reasonably depreciate the rule of division altogether, as quarrel with Horner's method because there is now and then a difficulty in ascertaining whether or no more than one figure will do to proceed with.

---

[*] He recommends that when more than *two* or *three* decimals of a root are wanted, the work should be turned over to *workmen* (*manœuvriers*) who are to be a distinct class from the mathematicians. The best comment on this will be to insert in this little *foot* note every figure of the work *for six* places of the equation on which this remark was made, with a guess at the *seventh*.

1	0	−2	5 (2·0945515

[*] As there is always a liability to defacement of figures, we give the sums of the digits in the horizontal and vertical lines. The sums in the horizontal lines should be 137, 115, 140, 157, 121, 10. The sums in the vertical lines should be 2; 32, 23, 27, 16, 24; 16, 25, 28, 25, 21; 20, 17, 29, 14, 25; 28, 23, 16, 20, 25; 27, 13, 30, 17, 26; 18, 16, 15, 26, 36.

[†] Mr. A. Davis, assistant master in University College School.

The same difficulty must exist in every method, as matters now stand. In the meanwhile, we think the discoverer of the process, which is now beginning to take its proper place, deserves attention to his request when he says, speaking of the antagonist claims which had started up—"All I ask of them (mathematicians) in recompense for the facilities consigned to their use in the non-figurate method, is to bear in mind that I alone am the author of it." And we have no doubt whatever, and are willing to stake our credit upon it, that when the inertia of the higher mathematicians in matters of computation is overcome, and when the mode of solving equations has reached the schoolboys, as it is rapidly doing, the name of Horner will be one of the household words of pure arithmetic, and himself looked upon as one of the greatest of its modern benefactors. Justice requires that his name should remain attached to his process.

IOD or IODO. A prefix used in chemistry to signify that the body to the name of which it is attached contains iodine substituted for some other element. Such compounds will generally be found described under the name of the body to which this prefix is attached.

IODAL ($C_4HI_3O_2$) *Hydride of tri-iodacetyl.* A body analogous to Chloral, said to be produced by mixing alcohol with nitric acid and then adding iodine. Its existence has not been satisfactorily established.

IODANILINE ($C_{12}H_6IN$). A derivative of aniline. [Aniline.]

IODHYDRIN ($C_{12}H_{11}IO_6$). A liquid compound produced by the action of hydriodic acid upon glycerin. [Glycerin.]

IODIC ACID. [Iodine.]

IODIDES. [Iodine. *Hydrogen and Iodine.*]

IODINE (I), a non-metallic, elementary, or simple solid body, discovered by M. Courtois, of Paris, in 1812. Its peculiar properties were however first ascertained by Gay-Lussac and Davy. Iodine exists in the water of the ocean and mineral springs, probably combined with sodium, or calcium, or magnesium; also in marine molluscous animals and sea-weeds; and has been met with in combination with silver. Iodine is principally obtained from *kelp*, or sea-weed which has been burnt for the purpose of obtaining alkali from it. When the alkaline and other salts have been separated from this ash, the residual solution is treated with sulphuric acid and binoxide of manganese, by which the iodine is set free, the decomposition being analogous to that by which chlorine is obtained by the same agency from common salt.

$$\underbrace{NaI}_{\text{Iodide of sodium.}} + \underbrace{MnO_2}_{\text{Binoxide of manganese.}} + \underbrace{2SO_3}_{\text{Sulphuric acid.}} = \underbrace{NaO, SO_3}_{\text{Sulphate of soda.}} + \underbrace{MnO, SO_3}_{\text{Sulphate of manganese.}} + \underbrace{I}_{\text{Iodine.}}$$

The process is conducted in leaden retorts of cylindrical form, and heated on a sand-bath to a temperature not exceeding 212° Fahr., a higher heat than this causing loss from the formation of chloride of iodine. At this temperature the iodine slowly vaporises, and passing off through the neck of the retort is condensed to the solid form in a series of flasks connected together by the neck of each passing through a hole in the bottom of the one preceding it.

Iodine is a soft opaque solid, of a bluish-black colour and metallic lustre. The primary form of the crystal is an acute rhombic octohedron. The crystals are usually flat. According to Gay-Lussac, its specific gravity is 4·947. When moderately heated, it rises in vapour of a violet colour, and hence its name from the Greek (ἰώδης, "violet-coloured"). On cooling, it again crystallises unchanged, nor is it altered by being subjected to very high temperatures; it has resisted all attempts to decompose it. Iodine has a strong disagreeable odour and taste, somewhat resembling bromine and chlorine; it stains the skin of a brownish colour, but not permanently. It is readily dissolved by alcohol, and the solution is of a reddish-brown colour; so little is taken up by water that a pound of that liquid will not dissolve more than a grain of iodine. It is very poisonous. Its characteristic property is that of giving an intense blue colour when added to a solution of starch. It unites with metals to form compounds, termed *iodides;* these are all decomposed by chlorine, or even bromine, iodine being liberated. They will be found described under the names of the respective metals. Iodine, like chlorine and bromine, forms acids both with hydrogen and oxygen.

The equivalent of iodine is 126·8; its combining volume, 2; and the specific gravity of its vapour, 8·716.

Oxygen and Iodine combine to form probably four compounds. When the vapour of iodine and oxygen gas are mixed at rather a high temperature, the violet tint of the iodine disappears, and a yellow soft substance is formed, which is regarded by Sementini as *oxide of iodine;* if this be subjected to the action of more oxygen gas, it is converted into a yellow liquid, which the same chemist supposes to be *iodous acid;* but the composition and properties of these compounds have not been accurately determined.

Iodic Acid (IO_5).—This compound was first obtained by Davy by the action of iodine upon what he called euchlorine gas. A better process however consists in heating the iodine in the strongest nitric acid. For this purpose the acid should be introduced with about a fifth of its weight of iodine into a capacious retort, and kept boiling for 12 hours; the iodine which rises and condenses on the sides of the retort is to be returned to the acid either by a glass tube or by agitation; when the iodine disappears, the excess of nitric acid is to be got rid of by evaporation. Iodic acid is a white semi-transparent solid substance, which may, however, be obtained in crystals containing one equivalent of water (HO, IO_5). It is inodorous, but has an astringent sour taste. It is so dense as to sink in sulphuric acid, and it deliquesces in a moist atmosphere. It is very soluble in water; the solution reddens vegetable blue colours; it detonates when mixed and heated with charcoal, sugar, and sulphur. When crystals of iodic acid are heated to 360° Fahr., they become anhydrous, and at about 700° are decomposed into iodine and oxygen. Iodic acid combines with metallic oxides to form salts, which are termed *iodates*, containing one, two, or three atoms of acid to one of base, and these, like the chlorates, yield oxygen when heated; an iodide remaining.

Periodic Acid (IO_7).—When chlorine is added to saturation to a solution of iodate of soda with excess of the alkali and concentrated by evaporation, a sparingly soluble white salt is obtained, which is *periodate of soda;* when this is dissolved in dilute nitric acid and mixed with nitrate of silver, a yellow precipitate falls, which, dissolved in hot nitric acid and evaporated, yields orange-coloured crystals of periodate of silver; these are decomposed by cold water, and an aqueous solution of pure periodic acid formed; this by cautious evaporation yields crystals, containing five equivalents of water of hydration. When heated to 212°, they are resolved into oxygen and iodic acid.

Nitrogen and Iodine appear to form three distinct compounds, containing respectively NH_2I, NHI_2, and NI_3, derived no doubt from ammonia (NH_3) by the substitution of hydrogen by iodine, thus:—

$$N\left\{\begin{matrix}H\\H\\H\end{matrix}\right. \qquad N\left\{\begin{matrix}I\\H\\H\end{matrix}\right. \qquad N\left\{\begin{matrix}I\\I\\H\end{matrix}\right. \qquad N\left\{\begin{matrix}I\\I\\I\end{matrix}\right.$$

Iodide of nitrogen, or probably, a mixture of the iodides, is best prepared by dissolving iodine in aqua regia, and pouring the mixture into strong solution of ammonia; it then precipitates as a puce-coloured powder; or iodine may simply be powdered and digested at once in the ammonia, when an iodide remains insoluble in the state of a dark brown powder. This compound is very explosive, especially when dry: the best method of exhibiting its power is that of allowing it to dry in small portions on bibulous paper, and then simply letting it fall on the ground or merely touching it, when it detonates with a sharp noise, heat and light being emitted, and the vapour of iodine and nitrogen gas evolved. It is not dangerously explosive in quantities of 3 or 4 grains.

Hydrogen and Iodine form hydriodic acid (HI), which may be prepared by the direct combination of its elements. When a mixture of iodine in vapour and hydrogen gas is passed through a red-hot porcelain tube, they combine to form this acid. It is however much more conveniently formed by heating in a retort ten parts of iodide of potassium, five of water, and twenty of iodine, and cautiously dropping in one part of phosphorus cut into small pieces; hydriodic acid then passes over in the state of a colourless gas, and may be collected by displacement in dry bottles. This acid has a sour taste, reddens vegetable blues, and when mixed with atmospheric air forms dense white fumes with its moisture: its odour resembles that of hydrochloric acid gas. It is soluble in water. The salts which it forms are termed *iodides.* When it is acted upon by metals, hydrogen is evolved, and when by metallic oxides, water is formed, and in both cases iodides result.

It is decomposed by oxygen when they are heated together; water is formed, and iodine evolved. It is also immediately decomposed by chlorine, which unites with its hydrogen to form hydrochloric acid, and iodine is set free.

Chlorine and Iodine form two chlorides. The *protochloride* (ICl) may be obtained by passing a current of chlorine gas into water in which iodine is suspended. A deep reddish solution is formed that yields irritating fumes possessing the smell of both the elements: it first reddens and then bleaches litmus paper. The *terchloride* (ICl_3) is best formed by acting upon iodine with excess of dry chlorine gas. It forms fine ruby-red crystals.

Bromine and Iodine form compounds corresponding with the chlorides.

Sulphur and Iodine.—Four parts of iodine and one of sulphur combine on the application of gentle heat, and yield a product of dark colour and radiated crystalline structure. It is easily decomposed by heat.

Phosphorus and Iodine unite in two proportions. The *biniodide* (PI_2) is formed by dissolving one equivalent of phosphorus in bisulphide of carbon, and adding two equivalents of iodine. On cooling the mixture to a very low temperature, acicular crystals of orange colour are deposited. The *teriodide* (PI_3) is produced in a similar manner to the last, three equivalents of iodine being used instead of two. It forms dark red tabular crystals.

Carbon and Iodine appear to form no true compound.

IODINE, *Medicinal Properties of.* Iodine, though only obtained in an isolated state in the year 1811, has been long employed as the efficient principle of other preparations and therapeutic agents, namely, burnt sponge and certain mineral waters. [Water, subsect. *Mineral*, in Nat. Hist. Div.] It is only since it has been procured as a distinct principle that its action has been ascertained with precision. In the present day it is administered rather in some artificial compound than as pure iodine, owing to its very sparing solubility in water. Iodine in substance, however, when applied to the skin, stains it brown, and even the very small quantity which can be dissolved in water is sufficient to cause rubefaction, and in the form of baths produces decided action both on the surface of the body and the general system. When applied to ulcers or any breach of the skin, it occasions heat and a sense of pricking and tingling; it is also absorbed, and may be discovered in the blood and secretions of the patient. Taken internally, even in small doses, it causes a sense of heat in the mouth and throat; if much diluted by the vehicle in which it is given, and the stomach be healthy, it appears to do little more than increase the digestive powers; but in larger and stronger doses it creates great heat in the region of the stomach, which becomes sensible to pressure, with a feeling of weight, heartburn, and often nausea and vomiting. In very large doses it acts as an irritant poison. It is not merely an irritant poison when taken in a large dose, but is a slow or accumulative poison, even when taken in medicinal doses for a length of time, inducing a peculiar state called *Iodism*. It has been generally represented as causing emaciation even to a frightful extent; but though this has occurred in some instances, it does not seem to be frequent, if we except the absorption of certain glands, especially the mammæ of females.

The diseases in which it has been found useful are glandular swellings, especially bronchocele or goitre, which rarely resists its action; in some strumous diseases, in chronic rheumatism, and also as an antidote against poisoning with strychnia, brucia, and verataria: but its claims to confidence are not clear in case of such formidable poisons. It is often of use in lessening the injurious effects of mercury and in the treatment of the sequelæ of syphilis. (See Lugol, 'On Scrofula.') A liniment composed of iodide of potass along with strong liquor ammonial and soap liniment, is extensively used in the hospital for consumption at Brompton, as a counter irritant. A mixture of tincture of iodine and tincture of opium, as an external application to the spine, is most useful [SPINAL IRRITATION], its use being suspended every three or four days; or a solution of iodide of potass in compound camphor liniment has the advantage of not discolouring the skin or linen.

IODOFORM (C_2HI_3). This compound, which is analogous to chloroform in its constitution, is prepared by adding an alcoholic solution of potash to one of iodine, till the colour of the latter is destroyed; care must be taken to avoid any excess of the alkali; the alcohol is evaporated at a gentle heat, and, as it goes off crystals of iodoform are deposited, which are to be washed with pure water to separate the iodide of potassium.

The properties of iodoform are:—It has the form of yellow brilliant laminæ, which have a slight disagreeable odour, somewhat resembling that of saffron; it is insoluble in water, but very soluble in alcohol, ether, and pyroxylic spirit. It sublimes at 212°, and decomposes at 248°, into carbon, iodine, and hydriodic acid. Its alcoholic solution decomposes very readily.

IODO-PYROMECONIC ACID. [MECONIC ACID.]

IODOQUININE. [CINCHŌNA, ALKALOIDS OF.]

IODOSULPHURIC ACID (SO_2Cl). An acid said to be formed when sulphurous acid is passed into a solution of iodine in pyroxylic spirit. Its existence is problematical.

IONIAN SCHOOL, comprises several of the earliest philosophers of Greece, whose speculations were predominantly of a physiological character, and who, with one or two exceptions, were natives of the Ionian colonies in Asia Minor. From this purely external circumstance the school has derived its name, and its members have been brought into an unbroken connection of masters and disciples by the learned labours of the later Greeks, who strove to give to the first development of philosophy the same orderly transmission of doctrine which prevailed in the later schools. Accordingly Anaximander is made the scholar of Thales and the teacher of Anaximenes, who had two disciples, Diogenes of Apollonia in Crete, and Anaxagoras, whose disciple was Archelaus of Athens, or Miletus, in whom the school closes. Now, not to mention that this purely artificial arrangement omits Heraclitus, the chief of the Ionians, it is also open to great difficulties both of doctrine and chronology. As regards the latter, however, we shall only advert to the general difficulty, that between six and seven generations (212 years) are occupied by the lives of Thales, Anaximander, Anaximenes, and Anaxagoras. The incongruity of the received arrangements appears at once on the slightest consideration of the doctrinal systems of the philosophers of this school. Agreeing in the hypothesis of a primeval state of things, they differed widely in the mode in which they accounted for the deduction of existing phenomena out of the primal substance. One theory endued the universe with life, and considered the orderly procession of all things to be a spontaneous development of a preexistent germ of life. A second accounted for all apparent alteration in the form and qualities of natural bodies by certain changes in the outward relations of space, and proceeded on the supposition of certain permanent material elements which change place in obedience to motion, either originally inherent in or extrinsically impressed on the mass. The latter is the mechanical, the former the dynamical theory of nature. Of the dynamical theorists, Thales first of all taught that all things are pregnant with life; that the seed or germ of vitality, which is in all things, is water, because all seed is moist and humid. Of this potentially living entity Anaximenes advanced a still worthier representation, and taught that the primal substance is infinite and sensuously imperceptible. This principle is analogous to the animal soul, and as the animal soul governs the body, so the universal soul rules and embraces all things. Diogenes made a still farther advance, and maintained that the harmony and design of the mundane fabric suggest the unity and intelligence of its first principle. This principle however he considered as simply physical, and only distinguished from natural phenomena in this, that while it is infinite, as the principle of all, they are finite. Still bolder was the flight of Heraclitus, who taught that the world is an everliving being, a rational fire, whose vitality involves a tendency to contraries, and is ever passing from want to satiety.

The mechanical theory is first opened by Anaximander, who flourished not long after Thales, who conceived the ground both of production and motion to be an eternal substance, which he called the infinite, and wherein the immutable elements were indistinguishably combined. Out of this chaos certain primary contraries, as he conceived them, cold and warm, earth and heaven, were first evolved, and in the course of certain separations and combinations alternately proceeding, more perfect forms are spontaneously developed, to be ultimately resolved into the homogeneous primary. After a long interval of a century Anaxagoras revived the mechanical physiology, and distinctly advanced the principle on which it rests, that nothing is changeable, but that the nature of every thing is permanent. Seizing the contrariety of the moving and the moved, which the mechanical theory is so well calculated to exhibit, he defined the latter to be extended antitypous bulk, inert body, infinitely multiple both in qualities and parts. The moving principle, on the contrary, is perfect, simple, and homogeneous—soul or spirit, which, as moving the elements into combinations of order and beauty, is endued with the faculty of knowing and surveying whatever was, and is, and shall be. Archelaus rather abandoned than advanced the views of his master Anaxagoras, and in him, as the teacher of Socrates, the Ionian school became extinct before the more extensive development of the Socratic philosophy.

(Ritter, *Geschichte d. Ionischen Philosophie*; and Brande's *Geschichte d. Griech.-Röm Philos.*)

IONIC DIALECT, the softest of the four written varieties of the Greek language, was spoken in the Ionian colonies of Asia Minor, and in several of the islands of the Ægean Sea. As the new Ionic, it is distinguished from an older, which was the common origin of itself and the Attic. The old Ionic was widely diffused, and its use was co-extensive with the Ionian settlements in the Peloponneseus and Northern Greece. (Thirlwall, 'History of Greece.') The language of epic poetry arose out of this original tongue, which after the Dorian conquest passed, on the one hand, with the fugitives into Asia Minor, while, on the other, it continued to be spoken, for awhile at least, by the conquered peasantry who remained in Greece Proper. This tradition, which however, like most of the earlier traditions of Greece, is involved in great obscurity, may perhaps serve to explain (what in the common legends of Homer is otherwise inexplicable) the similarity of the language employed by Homer and Hesiod, who, though near to each other in time, were widely separated in the supposed scenes of their poetical labours. This first matured form of the Ionic has been called the epic, and was faithfully adhered to as the standard of Greek epic and elegiac composition by all subsequent writers of epos or elegy, which also owed its birth to Ionians.

On the formation of the new Ionic, or simply the Ionic, great influence was exercised by the commerce of the Ionians, and especially by their intercourse with the soft and effeminate Asiatics. Neglecting the combination of strength with softness which gave to the epic dialect its characteristic fulness of tone, the Ionians attended only to mellowness and euphony, to attain which they softened the aspirates, accumulated vowels, and laid aside every broader and harsher sound. Herodotus (i. 142) distinguishes four varieties (*χαρακτῆρες γλώσσης*) of the new Ionic, in one of which he wrote, and, though a Dorian, has left us the best and most complete specimen of it.

IONIC ORDER. [COLUMN; GRECIAN ARCHITECTURE.]

IPECACUANHA is an emetic substance, the root of several plants growing in South America. All the kinds have nearly the same ingredients, but differ in the amount of the active principle which they respectively contain, termed emetina. The best is the annulated, yielded by the *Cephaëlis ipecacuanha*, a small shrubby plant, native of Brazil and of New Grenada. Of this sort there are three varieties, namely, the brown, red, and gray, or gray-white, called also greater annulated ipecacuan. As this is the only sort sent from Rio Janeiro, it is sometimes called Brazilian or Lisbon ipecacuan. It is sent in bales, barrels, bags, and serons. The root is in pieces from two to six inches long, and about the thickness of a straw, much bent or twisted, either simple or branched, with a remarkably knotty character, owing to numerous circular depressions or clefts, which give the whole an appearance of a number of rings; and hence the term annulated. It consists of a central axis called *meditullium*, and an external portion, called the *cortical* part. One hundred parts of good ipecacuanha consists of 80 parts of cortex and 20 of meditullium. Each contains emetina; but by far the greater portion exists in the cortical. Of the three varieties of annulated ipecacuanha the Brown contains 16 per cent. of emetina, while the red contains only 14 per cent.; the gray has not been analysed.

Another sort of ipecacuan is obtained from the *Psychotria emetica*, called striated; this kind contains only 9 per cent. of emetina, and the undulated or amylaceous ipecacuan, the produce of the *Richardsonia scabra*, holds only 6 per cent. of emetina, with 92 per cent. of starch. Besides these, the roots of numerous other plants are used in tropical countries as emetics, and often termed ipecacuan.

The dust or powder of ipecacuan applied to any mucous surface causes irritation and increased secretion from the part. It is chiefly employed to excite the stomach either to augmented secretion or to invert its action, and effect vomiting. It is also capable, by being combined with other substances, of being directed to the skin, and producing increased perspiration. When given in very small doses, it improves the appetite and digestive powers; in a somewhat larger dose, it acts on the intestines; but in a still larger, it inverts the action of the stomach, and occasions vomiting. It may therefore be used in a great many diseases, such as indigestion, dysentery, rheumatism, common colds, croup, &c. [Emeta; Emetics; Diaphoretics; Antidotes.]

Some caution is requisite in using it, especially with children, as it has a great tendency to produce sleep, and deep depression sometimes follows its use. When an emetic action is required, powder having a nauseous odour is preferable,; when a diaphoretic action is desired, as at the commencement of a common cold, ten or fifeen drops of ipecacuan wine are proper, out of any mild warm drink.

In case of violent vomiting from an over-dose, infusion of strong tea or oak bark may be given, and a mustard poultice applied to each side of the neck.

IPECUANIC ACID ($C_{28}H_{18}O_{14}$?). An acid of doubtful composition, found in the root of the *Cephaëlis ipecacuanha*. It is amorphous, red-brown, and very bitter. It gives a green colouration with persalts of iron, and a violet-black with ammonia.

IPOMÆA PURGA. [Jalap.]

IPOMIC ACID. [Sebacic Acid.]

IRIDESCENCE. A term applied to those brilliant colours which appear on substances presented in very thin plates, such as the soap-bubble, the laminæ of mother-of-pearl, &c. [Interference.]

IRIDIOCYANOGEN (IrC_4N_2) is a hypothetical compound radical. It forms with hydrogen iridiocyanic acid or hydroiridiocyanic acid, and with potassium an iridiocyanide of potassium. The latter occurs in the form of colourless crystals, and gives a deep indigo blue with the salts of peroxide of iron. This is one of the many compounds of a metal with cyanogen, like ferrocyanogen, and which have all the power of combining with other metals possessed by that body. Thus there are cobaltocyanogen, chromocyanogen, platinocyanogen, &c. [Cyanogen.]

IRIDIUM (Ir). An elementary metal occurring in certain ores of platinum. [Platinum, in Nat. Hist. Div.] It was discovered in 1804 by Tennant, but has since been more minutely examined by MM. Deville and Debray. The following is the method recommended by those chemists for the extraction of iridium from the other metals with which in nature it is always associated. The impure chloroiridiate of ammonia obtained in the preparation of the metal ruthenium [Ruthenium] is dried and calcined, and the resulting powder subjected to a stream of hydrogen, whereby all traces of chlorine and oxygen are removed. Platinum and some osmium are now extracted by aqua regia, and ruthenium separated by fusion with nitre and caustic potash, the alkaline salts being dissolved out by water. Any osmium that remains may be dissipated by the oxidising flame of the blowpipe, and the pure iridium fused in the oxyhydrogen lime furnace.

The colour of iridium is pure white, somewhat resembling polished steel. At the ordinary temperature it is scarcely malleable, but at a bright white heat it is perfectly so. The specific gravity of iridium is 21·15; its equivalent, 98·56. In the pure state it is unacted upon by acids.

Iridium and oxygen combine in three different proportions forming

Protoxide of iridium	IrO
Sesquioxide of iridium	Ir_2O_3
Binoxide of iridium	IrO_2

The *protoxide* is a black powder obtained on decomposing the dry protochloride with solution of potash. It is difficultly soluble in acids, but is rapidly attacked by alkalies. The *sesquioxide* is formed when the finely divided metal is ignited in a current of air; it is a bluish-black powder. The *binoxide* is, according to Clauss, always precipitated as an indigo-coloured hydrate when either of the chlorides of iridium is boiled with an alkali.

Iridium and sulphur form combinations corresponding to the oxides, and may be obtained by passing sulphuretted hydrogen through solutions of the respective oxides in acids. The *protosulphide* (IrS) is yellowish brown, the *sesquisulphide* (Ir_2S_3) brown-black, the *bisulphide* (IrS_2), like the protosulphide, but darker.

Iridium and chlorine form three compounds:—

Protochloride of iridium.—($IrCl$) is formed on passing chlorine gas over finely divided iridium heated to incipient redness. It is a dark olive-green powder, insoluble in water, and but sparingly soluble in acids, but when fused with potash and the resulting oxide dissolved in hydrochloric acid and evaporated to dryness, the protochloride remains as a transparent yellow mass readily soluble in hot water.

Sesquichloride of iridium sublimes when the finely divided metal is strongly ignited in a current of chlorine. In this state it is insoluble in water, but when prepared by oxidising iridium with fused nitre, and digesting the residue in hydrochloric acid, then forms with water a red-brown solution.

Bichloride of iridium ($IrCl_2$) results when chlorine gas is passed through water in which chloro-iridiate of ammonia is diffused. With alkaline and other salts bichloride of iridium forms double salts corresponding in composition to the analogous platinum compounds.

Iridium and carbon. When metallic iridium is held in the flame of a spirit lamp, a soft, dark gray powder forms on its surface, owing to the penetration of carbon from the spirit into the metal.

Iridium forms combinations with *phosphorus* and *iodine;* its oxides also form *salts* with some oxygen acids, but the resulting compounds have been little studied.

Iridium-black, having qualities very similar to platinum-black, is precipitated on boiling an alcoholic solution of bisulphate of iridium.

The *alloys of iridium* produced in a well fused state by the employment of the oxyhydrogen lime furnace described by MM. Deville and Debray ('Annales de Chimie et de Physique' for August, 1859) possess properties that render them exceedingly valuable in the arts. Thus the platinum alloy, containing 21·3 per cent. of iridium, is perfectly malleable, and may be worked into vessels possessing greater rigidity than if constructed of platinum alone. Such vessels, moreover, are quite unacted upon by acids, and the operation of dissolving platinum in aqua regia may be conducted in them without risk of their surface being acted upon.

The *derivation* of the word Iridium is from *Iris*, the rainbow, being suggested by the many tints assumed by solutions of the oxides of this metal.

IRIDIUM-BLACK. [Iridium.]

IRIS. [Rainbow.]

IRI'TIS is an inflammation of the iris, the membrane that surrounds the pupil of the eye. [Eye, in Nat. Hist. Div.] It most frequently originates in a disordered state of the system, as in gout or syphilis, but it sometimes follows the exposure of the eye to an intense light, or is produced by external injury, as the wound which is made in the operation for cataract, &c.

Iritis is principally characterised by an effusion of lymph, both into the subetance of the membrane, producing a peculiar dullness of its colour, and on its surface in the form of small masses which adhere at the edge of and around the pupil. The eye is at the same time irritable to light, and the pupil is closely contracted; there is redness of the conjunctiva, and a zone of a bright pink colour is usually seen surrounding the margin of the cornea.

Iritis is very likely to end in adhesions of the iris to the adjacent parts, by the lymph which is deposited upon it becoming organised, and having its vessels united with theirs; in which case, irregularity in the form of the pupil, a loss of its power of contracting and dilating, or even its complete closure and obliteration, with corresponding degrees of obscurity of vision or total blindness, may ensue. These results may be produced in a few days; and the treatment must therefore be prompt and vigorous. Blood should be drawn by cupping or leeches from the head or neck; mercury is usually administered in frequent and full doses till salivation is produced, and belladonna should be applied to or around the eye, to produce dilatation of the pupil and thus prevent its being closed.

IRON, *Medical Properties of.* Iron, in a purely metallic state, does not exert any appreciable influence over the human system. Nevertheless metallic iron is recommended as an antidote to poisoning by the salts of copper. Iron filings have been administered with a view to precipitate the copper in a metallic and therefore innocuous state. White of egg is a more prompt and generally more accessible antidote. The employment of iron filings to absorb fœtid exhalations from the feet is less beneficial than that of recently prepared and freshly powdered charcoal, put every morning into the shoes of those afflicted with this annoyance. Iron filings are sometimes prescribed medicinally, but before any marked effect can be produced by them, the metal must become an oxide or a salt; the presence of any acid in the stomach or alimentary canal promotes this change, while alkalies retard it. This form has been adopted in the treatment of worms, chiefly from the notion that the worms would be annoyed and dislodged by the mechanical irritation of particles of iron. This is an erroneous view. [Anthelmintics.] Tincture of sesquichloride of iron in infusion of quassia is extremely beneficial in all cases of worms, but its efficiency depends on its tonic and astringent properties.

A few only of the preparations and uses of iron can be given here. Sesquioxide of iron (rust, or the subcarbonate of some pharmacopœias), has been given in tic douloureux, in very large doses; in some instances with success. It is likewise useful in some cases of spasmodic contractions of the joints. The very large doses in which it is required to be given is a serious impediment to its use; for not only are the patients averse to it, but it clogs the intestines, which require to be frequently cleared out by a brisk cathartic. It is less objected to when given in London porter, a very suitable vehicle.

The black oxide is not so liable to objection, as it is more readily soluble in the fluids of the alimentary canal.

Ammonio-chloride of iron possesses no advantage over the simple chloride; the tincture of which, called tincture of sesquichloride of iron, is extremely valuable as an emmenagogue; it likewise is very beneficial in checking menorrhagia proceeding from relaxation of the uterus. It checks hæmaturia from relaxation of the tissue of the kidneys. In catarrh of the bladder it is very serviceable. In frequently repeated small doses it relaxes spasmodic stricture of the urethra. But the feeling of nausea and sinking which it causes, renders patients averse to its repetition. It acts as a potent astringent when applied externally or to mucous membranes as an injection.

Sulphate of iron can be given in small doses, in pills or otherwise. Its powers are often much heightened by combination with sulphate of quinia. In nervous debility and indigestion this form is valuable.

The potassio-tartrate of iron has less unpleasantness of taste than most of the other preparations of iron, and is therefore more acceptable to children, to whom also the vinum ferri is much prescribed. Both these are nearly superseded by the citrate or ammonio-citrate of iron, which can be given in the form of lozenge or syrup. The latter given in warm water or lemonade is relished by most children. Still the potassio-tartrate has many recommendations.

Iodide of iron is a preparation of great value in strumous disorders.

The same may be said of the phosphate of iron, a preparation formerly in the 'London Pharmacopœia,' and now most unjustly excluded from it. In the phosphatic diathesis of feeble subjects, with a tendency to rickets, it is invaluable. The dose for children is a very few grains, cautiously increased. The numerous preparations of iron recently introduced by chemists have not been sufficiently tried to permit them to be spoken of with certainty; but in many cases their utility is obvious. Of these the chief are citrate of iron, potassio-citrate, sodio-citrate, zinco-citrate, magnesio-citrate, ferro-citrate, and citrate of quinine and iron; this last is of great service in tic douloureux.

A better form is the pyro-phosphate, which is soluble in water, warm or cold; the form of this in pseudo-crystalline scales, is a pyro-phosphate of iron and soda. This along with rhubarb is a most efficacious cure for the headaches of most young females.

The saccharated carbonate of iron has many advantages. It may quite supersede the well-known Griffith's mixture. Hydrated proto-sulphuret of iron is stated to be an antidote to poisoning by corrosive sublimate, but to be of use it must be given within ten minutes after the poison has been taken. White of egg is a better antidote.

Chalybeate waters often furnish the best medium for administering iron; especially when the iron is associated with much free carbonic acid. Where no free carbonic acid is present, and in some instances even where it exists, the water of the springs should be received in and drunk out of *warm* water. This often prevents the spasm which is apt to occur when very cold water is suddenly taken into the stomach.

Besides being reputed an antidote to the poisonous salts of copper, iron is asserted to prove an antidote to other violent poisons.

Hydrate of peroxide of iron, called also hydrated peroxide of iron, is considered a trustworthy antidote against arsenic, if administered promptly, while the arsenic is yet in the stomach, and not absorbed. Prussic acid may be decomposed or combined, so as to be rendered innocuous, by giving promptly, first, solution of carbonate of potass, followed by a very diluted solution of the proto-persulphate of iron; the object being to form a ferro-prussiate of potass in the stomach. (See 'Lancet,' 5th October, 1844; or 'Pharmaceutical Journal,' vol. iv. p. 373.)

Physiological Effects and Therapeutic Employment of Iron.—Iron exists both in plants and many animals, as the mammiferæ and birds, constituting an essential part of their fluids and solids; but, incorporated as it is thoroughly with them, it gives rise to none of those phenomena which it occasions when taken into the stomach. Upon the living tissues iron has a tonic influence; and as its preparations greatly promote digestion, they excite the appetite and render more easy the elaboration of the aliment. The vitality of the digestive organs being exalted, they extract from the food more of the nutritious principles, and thereby furnish a greater quantity fit to be assimilated.

These beneficial effects are best seen when the medicine is given in small and long-continued doses, or in the greatly diluted state in which iron occurs in the mineral waters or chalybeate springs. On the other hand, chalybeates occasion at times, especially if in large doses, pain of the epigastre, nausea, fœtid eructations, and great anxiety; consequences referable to the immediate impression, a sort of constrictive action, which the preparations of iron make or exercise when they reach the stomach, upon its internal surface, and the nerves which are distributed upon it. The unpleasant effects may generally be avoided by giving it at first in very small doses, gradually increased, or by diluting it with some vegetable substance of little activity.

Iron given in large doses, when it reaches the intestines, produces in some persons obstinate constipation, accompanied with a sense of great heat in the lower belly; in others it occasions colics and frequent alvine dejections; while with a third set of persons none of these effects follow its administration.

During the use of iron the fæces invariably become blackened, which is caused by the tannin of our food acting upon the iron.

In respect to the secondary effects of iron, the amount of these depends upon the quantity absorbed, and the length of time it has been given. That it is absorbed, in most instances, and carried into the circulation, is proved both by the effects of it being felt over the whole system, and by being distinctly recognisable in the urine on the addition of an infusion of galls. When used for some time, chalybeates increase greatly the power of the heart; the pulse becomes stronger and harder—effects most observable upon persons previously enfeebled by disease. If persisted in, they cause increased arterial action, followed by febrile commotion, sense of heat, and hæmorrhagic discharges from different parts of the body. These phenomena show themselves most speedily in persons of a plethoric habit and sanguine temperament; iron also rouses the absorbent organs when sluggish.

The functions of nutrition and assimilation are greatly heightened by the use of iron; but if it be too long persevered in, diseases of over-action ensue, as inflammations, hæmorrhages, &c. These symptoms indicate the necessity of discontinuing it.

The preparations of iron are unquestionably efficacious in diseases which proceed from a relaxation of the substance of the living tissues, from an inactivity of the reparative or assimilative function, or in case of weakness proceeding from deficient supply of nervous energy.

Hence they are indicated in anæmia, in convalescence from debilitating fevers, and other tedious diseases, as well as after some of the more acute phlegmasiæ, as pneumonia, the cough remaining after which, if not occasioned by any organic change, is sooner removed by preparations of iron or bark than any other means. Chalybeates are likewise given in defective menstruation from debility of the uterus, and sometimes in sterility. In chlorosis iron is almost our sheet-anchor, while it is also very serviceable in some forms of dyspepsia, also in worms, (in which the sulph.-ferri is given in large doses), in passive hæmorrhages, and it is prescribed empirically in many of the cachexiæ, as scrofula.

Chalybeates are found useful in many nervous diseases, as hysteria: the cough which is often present in these complaints may be effectually removed by preparations of iron. The indurations, too, of the mammæ (apt to be considered of a cancerous nature), and of other glands in hysterical females, are often dispersed by the use of iron. Some of the forms of tic douloureux, not dependent upon organic causes, are often cured by chalybeates. Iron has likewise been prescribed in the intervals of the paroxysms of intermittents, particularly quartans. The sulphate is given in the dose of ʒi. in a pint of water,—in which circumstance it can only act beneficially, like cinchona or bitter tonics,—iron being among minerals what bitter herbs are among vegetable remedies.

Chalybeates are *contra*-indicated in plethora and all inflammatory diseases, as well as active hæmorrhages, as also during pregnancy in females of a sanguine temperament.

IRON MANUFACTURE AND TRADE. The art of smelting iron was practised in this country during the time of the Roman occupation. The principal seats of the manufacture appear to have been Sussex and the Forest of Dean, or Arden as it was then called. It is known that iron-works existed in that part of Gloucestershire in 1238; because there occurs among the patent rolls of Henry III. of that date, one entitled 'De Forgeis levandis in foresta de Dean.' Remains of ancient iron-furnaces have been noticed in Lancashire, Staffordshire, and Yorkshire. The art of working in iron and steel was much practised in this island before the Norman conquest. We are told that not only was the army of Harold well supplied with weapons of steel and with defensive armour, but that the horses were covered with steel and iron armour, and that every officer of rank maintained a smith, who constantly attended his master to the wars, and took charge of his arms and armour to keep them in proper repair.

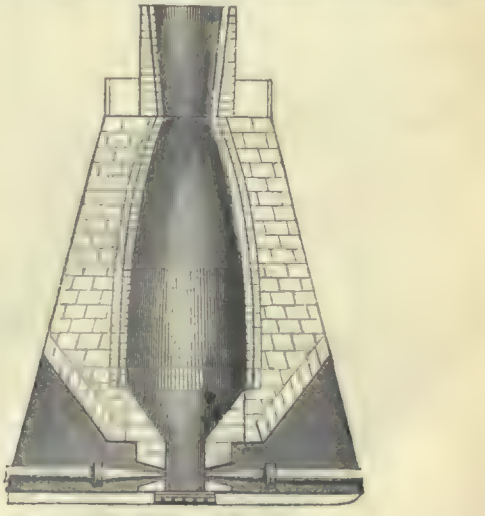

Fig. 1.—Vertical Section of Blast Furnace.

There are three principal qualities into which this metal is commonly divided, namely, pig-iron, cast-iron, and malleable or bar-iron, the second and third being the results of an extension of the processes necessary for the production of the first.

Pig-iron.—The first process is that of reducing the iron-stone or ore, or, as it is technically called, the *mine*, into a metallic state by means of fusion. This operation is conducted in a *blast-furnace*, the form and construction of which will be understood from the following section. The interior of this furnace in the broadest part, which is called the *boshes*, is usually from 14 to 17 feet in diameter, and this is gradually decreased to about half that diameter at the top. The whole is built of masonry, the lining to the furnace being composed of fire-bricks carefully jointed together with fire-clay: the whole furnace is strongly bound together with iron hoops or stays. The furnace is again contracted below the boshes, and into this lower part the melted iron falls as it is formed. The ground-plan of this lower part of the furnace is constructed as shown in the following diagram, where the unshaded square in the centre represents the *hearth*, and is about 3 feet square. The three tubes leading to this hearth (two of which are shown in the vertical section), and which are called *tuyeres*, are used for introducing the blast of air required to give the degree of intenseness to the heat necessary for fusing the ore.

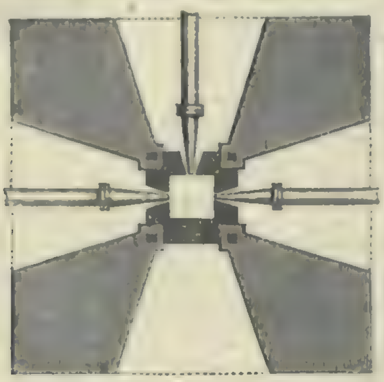

Fig. 2.—Ground Plan of Blast Furnace.

The size and form of the blast furnaces have undergone much change. Slight differences will be observed by comparing the section in *fig.* 1, with that at col. 241 of the article FURNACE; but the modern alterations have been still more considerable. Half a century ago the furnaces were generally about 40 feet high, 10 or 12 feet across the boshes, and 3½ feet diameter of tunnel-head, or cylinder, at the top; and they were blown with only one tuyere each. By degrees the tunnel-head has been enlarged to 10 feet; the tuyeres have been increased from one to three; a new form has been given to the lower part of the interior; and in some instances, such as that of Messrs. Dixon's works at Govan, near Glasgow, the whole furnace is made cylindrical. The largest furnaces are now 60 feet high, and about 40 feet square at the base. Engineers are still divided in opinion concerning the best size of the *throat*, or contracted part between the body of the furnace and the tunnel-head; but all agree that it should be much longer than those formerly employed.

We have now to notice the filling of the furnace with iron-ore, coke, and limestone. The ore must previously have been roasted or calcined in a kiln, in order to drive off the water, sulphur, and arsenic, with which it is more or less combined in its native state: by this process it loses one-sixth part of its weight. One of the recipes for smelting iron, in use a few years ago, gave the proportion at 15 tons of roasted iron-ore, 22½ tons of coke, and about 6 tons of limestone; but these proportions vary according to the quality of the ingredients, and the routine of processes. The ingredients are supplied at equidistant charges, and must be intimately mixed together in the furnace. The limestone must be broken into small pieces; its use is to act as a flux to the ore and promote its fusion. The mode of filling the furnace varies a good deal. In Wales, the blast furnaces are usually built on the slopes of hills, so that the minerals can easily be brought from the mines to the top of the furnace; but where the latter is built on the level of the ground, as in most of the midland districts, the minerals must be raised to the proper level by steam, water, or pneumatic power. Inclined planes have generally been used; but these are in many works being superseded by a direct vertical lift. One of the filling-mouths at the top of a furnace (of which there are sometimes four) is shown in *fig.* 3. The usual plan is to throw in the ore, coal, and limestone in alternate barrowsful; but Mr. Slate, in 1859, proposed a new method. He makes the furnace-mouth very wide, and places over it a bridge supported by iron girders. A cast-iron pipe descends vertically from the bridge into the furnace, and is continued down beneath the surface of the burning material; the greater portion of the fuel is fed in through this pipe; while the other materials are fed in through the open mouth of the furnace; insomuch that the fuel is always in the middle, and the ore and flux around it. A valve lifts up the cover of the central pipe; and several scuttles or openings are left to admit the other materials. How far the cast-iron pipe will bear the intense heat, is a point not yet satisfactorily determined.

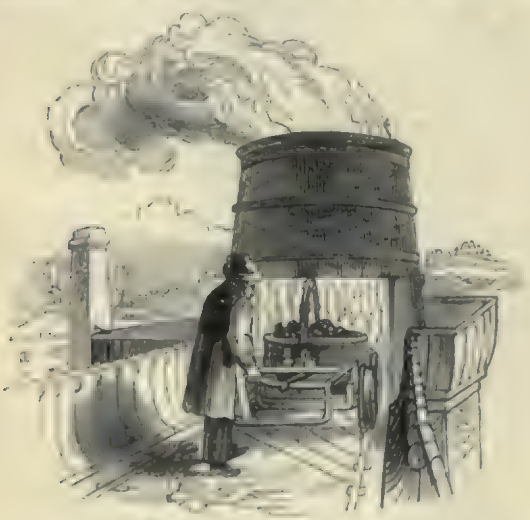

Fig. 3.—Filling Blast Furnace.

Supposing the fire to be lighted and the minerals introduced, the next matter is the important one of the *blast*. The heat that would be produced in any furnace by merely setting fire to the fuel which is thrown into it would be altogether insufficient for the fusion of the ore, if its intensity were not promoted by the forcing in of a current or blast of air. For this purpose it is necessary to use a strong mechanical force. Water-wheels, where they can be had, are suitable agents; but there are not many places where a sufficiently copious and regular supply of water at all seasons can be commanded, and the success of an iron-work would be destroyed by the failure of the blast in any degree for even a short time. Steam-engines are now, therefore, almost universally preferred. This power is applied to the working of a blowing cylinder, which may be many times the area of the cylinder of the steam-engine. If the blast thus produced were passed immediately from the blowing cylinder through the tuyeres to the furnace, the effect would be intermitting and irregular, ceasing at the end of each stroke of the steam-piston. To remedy this inconvenience the blast is carried into an intermediate chamber of a spherical or cylindrical shape, called a regulator; and as the air is in a state of condensation when admitted, its effort to expand itself again to its natural volume causes the continuous and regular supply to the furnace which is necessary. The air thus forced into the furnace keeps the heat at a high degree of intenseness. Until about thirty years ago, the air thus supplied was uniformly at the temperature of the atmosphere from which it was immediately taken; and the effect was not only to produce a stream of cold air, but also to supply a quantity of moisture which is prejudicial to the smelting process. Atmospheric air always contains moisture in some degree or other, but holds a larger proportion in hot than in cold weather, for a very obvious reason, and this causes the furnaces not to work so well in summer as in winter. By the previous drying and heating of the air these inconveniences are remedied, the consumption of fuel is lessened, and the absence of moisture is said to have a beneficial effect upon the quality of the iron produced. This improvement was the invention of Mr. Neilson, of the Clyde iron-works, and was made the subject of a patent in 1829. The air, before it is forced into the furnace, is heated in cast-iron vessels to 300° Fahr., or more, and is thus more nearly than when at its natural temperature in a condition to support combustion.

The precise value of the hot-blast has been a subject of very animated controversy. That it has contributed greatly to the advance of the manufacture is beyond all question; but some persons appear to carry this estimate to too high a degree. Just before Mr. Neilson introduced his method at the Clyde Works, it was customary in that establishment to use eight tons of coal for making one ton of iron; in the next following year the quantity was reduced to five tons and a quarter, with an addition of eight cwt. for heating the air before using. In 1831, Mr. Dixon, of Calder Works, found that if the temperature of the blast were raised far above 300° Fahr., raw coal might be used instead of coke in the blast furnace—a most important discovery, for it rendered unnecessary the cost of time and money in coking the coal for making certain descriptions of iron. From that time it became usual to raise the blast to 600° Fahr., about sufficient to melt lead or zinc. In 1833, it was asserted that three tons of coal sufficed, including that for heating the air, for smelting one ton of iron; and that the same quantity of air would blow four furnaces as had previously been used for three. The hot-blast has from the first been more favoured in Scotland than in Wales or in Staffordshire; nevertheless it is increasing everywhere in use. Mr. Truran takes exception to some of Mr. Mushet's statements concerning the enormous saving effected by using the hot-blast. He contends that only a part of the economy now unquestionably observed in the manufacture is due to this cause, the rest being traceable to other improvements. He shows this by adducing the important fact that furnaces, in which the hot-blast has never been employed, continue to increase their produce. This has been especially observable at the great Dowlais Works, near Merthyr Tydvil, where the economising of fuel has been very great without any change in the temperature of the blast. Mr. Truran attributes these improvements partly to an increased use of carbonaceous ironstone, and partly to an enlargement in the throat of the furnace, which facilitates the use of raw coal as a substitute for coke. At the Plymouth and Duffryn Works, one in Glamorganshire and the other in Monmouthshire, the yield has gradually increased to 130 tons of pig-iron per week, from an average of much less than half that quantity, without any departure from the old cold-blast. Some of the steam-engines now employed to send the blast into the furnaces are quite stupendous. The blowing cylinder of the engine at the Dowlais Works is 144 inches in diameter, and makes 19 strokes per minute, with a length of stroke of 12 feet: it sends in 50,000 cubic feet of air per minute, at a pressure of 3 lb. on the square inch; and its boiler-furnaces consume a ton of coal per *hour* to raise the necessary steam.

The blast, whether hot or cold, having done its work, the metal contained in the ore has become liquefied, and is then ready for removal. The iron is run from the furnace every twelve hours, by tapping it in the front, on a level with the bottom of the hearth, at the side on which, as will be seen from the diagram, there is no tuyere introduced. When the furnace is tapped, the metal is allowed to run into channels formed in the sand of the smelting-house floor. The names of *sow-metal* and *pig-metal*, which were originally given by the workmen, signify in one case the blocks of iron which are formed in the large main channels, and in the other case the smaller blocks which are formed in smaller side channels communicating with the larger ones; these names were adopted from the fancied resemblance of the cast metal to a sow and her litter of pigs. This is iron in its crudest state. The weight of materials lost in its production is somewhat greater than that of the fuel used; taking into account the refuse cinder and ashes with the metal, the whole does not weigh quite so much as the ore and lime that have been put into the furnace. Large heaps of cinder are gradually accumulating in the neighbourhood of iron-works, and give a dreary aspect to the country.

The quality of pig-iron varies according to the purposes for which it is intended, and depends not only upon the quality of the ore, but also upon that of the fuel. The principal division is into *foundry-iron* and *forge-iron*, the former being used for castings, the latter for conversion into malleable iron. Foundry-iron is further divided into three qualities, distinguished by the numbers 1, 2, and 3. No. 1 contains a large proportion of carbon, which it has acquired from the coke used in smelting, and the quality of which has been chosen with a view to the production of this kind of iron; it is soft and very fluid when melted, so that it will run into the finest and most delicate forms the moulder can produce. No. 2 contains a smaller proportion of carbon; it is harder than No. 1, closer grained, and of more regular fracture; it is more refractory in the furnace, and does not run so freely when melted as No. 1; but as it is harder and stronger, it is preferred for purposes where strength and durability are required in preference to delicacy of form: these two kinds are unfit for conversion into bar-iron. No. 3 varies in the same direction as No. 2, but in a greater degree, from the qualities of No. 1; it is used for many kinds of heavy work, where it has to bear great strains and is exposed to constant wear. Forge-iron is divided also into three qualities, and is distinguished as *bright-iron*, *mottled-iron*, and *white-iron*, which names are indicative of the appearance each quality presents to the eye. They all of them contain some carbon, but less than foundry-iron, and in proportions diminishing in the order in which they are here mentioned, white-iron having the smallest proportion of any, and being exceedingly hard; its fluidity too is so small that it runs with difficulty into the channels provided to receive it at the first smelting, and it is altogether incapable of being afterwards used for foundry purposes.

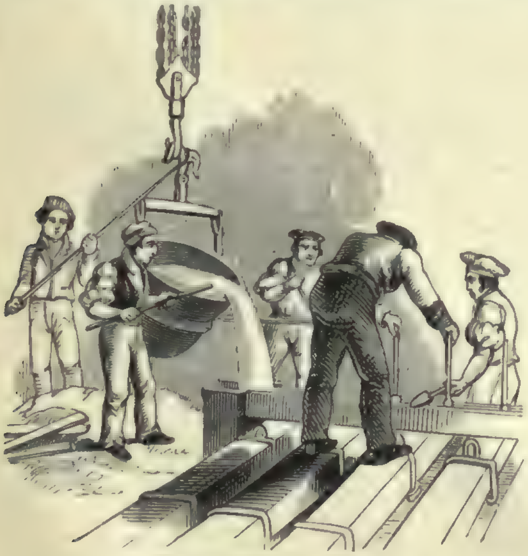

Fig. 4.—Casting Iron Pipes.

Cast Iron.—Of casting or founding we need not speak here; it has been sufficiently noticed under Founding, and under other headings cited in that article. One of the modes of casting iron-pipes is shown in *fig.* 4.

Malleable-iron.—This, which is also called *forge-* or *bar-iron*, is pig-iron freed from carbon and oxygen. The first operation for producing this change is called *refining*. It is performed in small low furnaces about three feet square at the base, having the bottom or hearth of fire-bricks, and the sides of cast-iron, made hollow to allow a stream of water to pass constantly through, which prevents their being quickly burnt away; near the top are holes for the insertion of blast-pipes. These refineries have iron doors at the back, but are open in front; the whole is surmounted by a chimney of brick-work carried to the height of 20 feet from the ground. At the level of the hearth in front is a hole similar to that in the smelting-furnace for running out the melted metal. This communicates with a flat mould of cast-iron 20 feet long and 2 feet wide, placed over a cistern of water with which its under surface is in contact, and which serves to cool the metal rapidly as it runs into the mould. The iron is kept in a state of fusion in the refinery for some time, exposed to an intense heat produced by a strong blast. From the sudden cooling to which it is exposed, the plate when run into the mould is very brittle: when broken the fracture presents a bright silvery appearance. From 22 to 23 cwt. of pig-iron is required to produce one ton of refined iron, and from 10 to 12 cwt. of coke is used for the purpose.

The iron being refined, the next process employed for making bars is called *puddling*, and is performed in a reverberatory furnace, thence called a *puddling-furnace*. The structure of this furnace will be explained by *fig.* 5. In this diagram *a* is the grate, which is supplied with coal through a door in the side. The refined metal broken in small fragments is placed in the body of the furnace *b*, over which the flame is made to play in its passage to the chimney, *c*. The degree of the draft is regulated by a damper on the top of the chimney, which is about 30 feet high. Such is the intenseness of the heat in these furnaces, that when the damper is raised the flame is sometimes carried to the top of the chimney. Compare this cut with one in the article Furnace, col. 240, for a few additional details. The quantity of refined metal put into this puddling-furnace at each charge is from 3½ to 4 cwt. In about half an hour from the charging of the furnace the metal begins to melt. The puddler then observes, through a small hole provided for that purpose and for the introduction of his tools, the progress of the work. The business of the puddler is so to dispose of the pieces of metal, moving them by means of his tools, as to ensure an equable application of heat to the mass. When the whole quantity is fully melted, the puddler stirs the metal about briskly, changing his tools continually that they may not be melted. By means of this agitation the metal gives off an elastic fluid, and after a time becomes thick, and grows increasingly so, until it loses all fluidity and forms into lumps. The contents of the furnace are then divided into five or six portions by the puddler, and each is made up by means of his tools into a roundish form. These balls are technically called *blooms*. Being taken from the puddling-furnace they are subjected each to several blows from a heavy hammer (called shingling), which makes them more compact and gives them a shape more convenient for going through the rollers. The form and construction of these rollers are shown in the following diagram. The bloom is passed in succession through the holes in *a*, beginning with the largest and proceeding to the smallest; or through the grooves in the second roller *b*; and is thus reduced to the requisite width and thickness. By these rollings the iron is converted from a fusible, hard, and brittle substance, to a tough and elastic bar which is hardly fusible, and which from its property of yielding and altering its form under the hammer has acquired the name of *malleable* iron. The quantity of refined metal required to

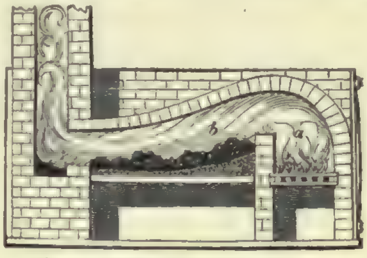

Fig. 5.—Section of Puddling Furnace.

make one ton of these rough bars is about 22 cwt., and the quantity of coal consumed in the process is about 17 cwt.

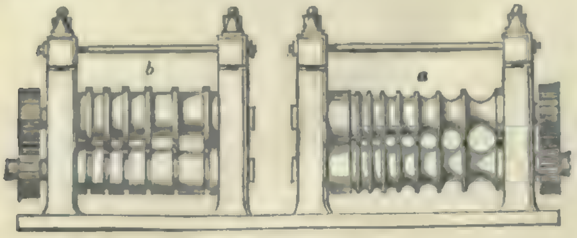

Fig. 6.—Puddling Rollers.

All the processes of refining, puddling, and blooming, like those of smelting, have undergone numerous improvements within the last few years. Refining is always needed for making the best iron; but it is not so much adopted as formerly for the medium kinds. Sometimes, instead of refining and puddling, a process called *boiling* is adopted; and this practice has of late been greatly extended. Those who 'boil their pigs,' as it is termed, do so under the impression that it obviates some of the waste involved in refining. The boiling-furnace differs in some particulars from the others. Into it is put a portion of hammer-slag, then pig-iron, and then fresh coal. The metal is kept almost in a boiling state for half an hour, the puddler working it about all the time; a cinder or heavy slag falls to the bottom, and the gradually-thickening iron is worked about into balls. As generally conducted, the melting occupies about half an hour, the boiling half an hour, and the balling an hour. All the manufacturers admit that refining and puddling produce the best iron; but they differ in opinion concerning the relative advantages of boiling for the middling and cheaper qualities. Boiling is less in favour in South Wales than in Staffordshire. When the iron has been worked about into balls or blooms, either by refining and puddling, or by boiling, the blooms are, as we have said, shingled, or beaten with a few blows of a heavy hammer; this is admitted to make the best iron; but the makers of inferior kinds prefer to use a machine called a *squeezer*, because it leaves some of the slag in the metal, and thereby increases the quantity. Mr. Brown, of the Oak Farm Ironworks, has recently introduced a machine for this purpose. Three excentric cams work simultaneously; they are kept rotating in one direction by wheels and pinions, worked by steam power. The convex sides of the cams are grooved and serrated. A bloom of white-hot iron being dropped into the concavity of the upper cam, it is drawn into the centre of motion of the three cams; the convexities approach nearer and nearer, and the serrations squeeze and knead the iron like dough. The slag and impurities are expelled, more or less completely, and fall out of the machine. By the approximation of the cams, the iron is sent out as a sort of cylinder. This may be the best place to notice a plan brought forward by Mr. Maudslay, in 1858, for producing cast-iron possessing a degree of toughness almost equal to that of the best wrought iron for the steam-engine manufacture. The plan consists in the employment of an entirely novel furnace, which revolves on an axis inclined about 10° from the perpendicular. The rotation is maintained by a system of gearing and toothed wheels, actuated by steam power. The iron being brought into a molten state in the furnace, and being kept constantly stirred, the two movements of rotation and stirring afford great opportunity for the sulphur and other impurities to escape from the mass and to fly off. The iron becomes semi-puddled; it retains a sufficient degree of fluidity to be cast into moulds, which fully puddled iron does not; while it has more fibre and toughness than pig or raw iron. The metal is, in fact, precisely in a medium state between pig-iron and malleable-iron.

Rolled Iron.—We shall adopt this as a convenient name for iron in a more advanced state. We have seen that the crude smelted metal constitutes *pig-iron;* that when this is run into moulds it becomes *cast-iron;* and that when the pigs have been refined and puddled, or boiled, the result is *malleable-iron.* This malleable iron is the substance from which are made bars, rails, nail-rods, wire, sheets, &c., all of which we may consider to be varieties of rolled iron, since they all pass between the nearly touching surfaces of ponderous iron-rollers.

When the blooms have been shingled or squeezed, and roughly rolled into bars, in the manner already described, and while yet hot, they are cut into convenient lengths and taken to the *balling-furnace*, the shape and construction of which resemble the puddling-furnace. In this balling-furnace the bars are piled evenly, so that one bar does not project beyond another. Several of these piles, each of which is composed of five or six bars, are placed at once in the furnace, and when sufficiently heated, so that they will weld together, the piles are taken out separately and are passed again through rollers similar in construction to those described above, but differing from each other in the form of their orifices and grooves, so that either round or flat or square rods and bars may be produced at the pleasure of the maker.

In the production of various kinds of iron from the malleable state, little more is necessary than to vary the rollers through which the iron passes, in their diameter, their power, their closeness, or the size and shape of their grooves. In some of the establishments, the roughing-rolls, or those first used, are of vast size and weight—as much as 6¼ feet long by 22 inches in diameter, requiring great steam-power to rotate them. Some of the achievements in rolling bars are very remarkable. When the Great Exhibition of 1851 was about to be held, the Rhymney Works in Monmouthshire produced the largest and heaviest rail ever made, being 52 feet long and weighing 1575 lbs. Thereupon, the workmen at the Tredegar Works voluntarily undertook, for the honour of their firm and not for pay, to produce a still larger rail; their specimen was 60 feet long, but a few pounds lighter than that from Rhymney. The rolling of iron into rails, bars, and rods is very similar in its character, seeing that there are grooves in the rollers for all these kinds. In producing sheet-iron, however, this is not the case; the rolls are smooth, and the gradual thinning of the sheet results from bringing the rollers more and more closely into contact. In preparing the sheets for various manufacturing purposes, a machine is sometimes used, one end of which cuts the iron as if it were a piece of pasteboard, while the other pierces it for the reception of rivets.

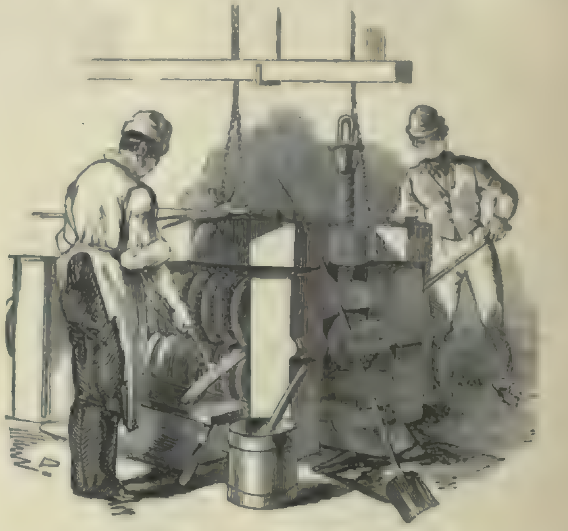

Fig. 7.—Rolling Bar-iron.

It is right to mention here, that the rolling of iron was one of the capital inventions of Richard Cort, who, by a series of scandalous actions on the part of a government officer, and laxity in official morality generally, was brought to utter ruin in the attempt to carry out a system which has greatly enriched the iron manufacturers of this country. The whole case is being minutely narrated by Mr. Webster, the barrister, in a series of papers in the 'Mechanics' Magazine' for 1859 and 1860.

Projected Improvements.—It is impossible to notice here all the novelties introduced or proposed in the iron manufacture within the last few years; but there are three concerning which a few words may be given: namely—the production of iron direct from the ore; the utilisation of slag; and the utilisation of the gases and heated air of the blast-furnace. The process introduced and warmly advocated by Mr. Bessemer will best be noticed in connection with STEEL MANUFACTURE.

The making of wrought-iron direct from the ore is now attracting much attention in the United States. The iron is in this case not puddled, as it never melts; but having first been deoxidised in a close chamber, it is simply welded together. There are many patented processes at work to this end. In one, Kenton's, the surplus heat from the reducing chamber passes round a series of tubes where the other processes are going on, insomuch that one mass of fuel avails for the whole operation. Another, Davis's, begins by pulverising the ore, mixing it with 20 per cent. of coal, putting the mixture into an air-chamber heated by anthracite, and thence passing it to a sort of puddling-furnace heated by the same fuel. A third, Harvey's, employs the gases generated in the furnace to act directly on the ore in deoxidising and desulphurising it, without making the puddling process a distinct one. The object of all these plans seems to be to save fuel and labour; but English manufacturers have not yet seen reason to place much reliance on the methods.

The utilisation of slag is an important matter, if practicable; for there are millions of tons of it lying waste, all of which is known to contain a certain per-centage of iron. Professor Bleekrode, in a communication to the Society of Arts in 1859, drew attention to this matter. Of the vast heaps of slag now existing some are modern, while some are the remains from ancient works. The Swedes make good iron from the slag of their old charcoal smelt-works, in a furnace suggested by Sefström in 1821. At Liege slag is mixed with the poorer ores, and smelted. The Silesian slag has been utilised since 1855, by mixing it with a certain per-centage of argillaceous schist and limestone. The same thing is done in Austria. The slag of the Dean Forest Works used to be made into a peculiar kind of black bottles at Bristol. Numerous processes have been patented in England within the last few years for rendering the slag useful, generally by mixing it with lime or limestone. Dr. Percy has recently observed: "An immense quantity of iron slag, far richer than many iron ores, is annually thrown away. It may be that the presence of phosphorus in sensible quantity is one of the causes which prevent the re-smelting of this slag with advantage. This fact has not yet sufficiently attracted the attention of those engaged in the manufacture of iron. The discovery of a method of extracting economically good iron from these rich slags would be of great advantage to the country, and could not fail amply to reward its author." Among the *seven million tons* of slag supposed to be annually produced in this country, many specimens are very beautiful when cast into moulds, looking like marble and serpentine when polished. Hence have arisen certain plans of utilisation, irrespective of the re-smelting for the sake of the metal. But there are drawbacks. If exposed to the air, the slag becomes oxidised and rusted; if not well annealed, it becomes friable; if in every way well prepared, it takes so much labour and fuel to work it that it ceases to be a commercially profitable material.

The third subject, the utilisation of waste heat, was taken up a few years ago by the Ebbw Vale Iron Company of South Wales. After a furnace has performed the work for which it is intended, various gases escape with the smoke, at the upper orifice; and these gases carry with them a large amount of valuable heat. If the heat could be abstracted and usefully applied, without lessening the power of the furnace, an economical benefit would result. The above-named company had eleven blast-furnaces, five engines to produce the blast, and twenty-five boilers to supply the engines with steam. The greater number of these boilers were wholly heated by the waste heat from the blast-furnaces; and various ovens and stoves in the works were heated by similar means. The heated gases were arrested near the top of the furnace, carried out by a horizontal tube, mixed with atmospheric air admitted in thin sheets or layers, and ignited by a small fire. It formed a true gas-light; and this gas-light heated a large flue, which was surrounded by a boiler containing water; and thus was a supply of steam obtained. These operations at Ebbw Vale depended on the combustion of the furnace gases; and the Ystalyfera Works modified the process by mixing the gases more thoroughly with atmospheric air. At the iron-works generally, however, it is considered that there are disadvantages which counterbalance the supposed saving; and neither plan has yet been very extensively acted on.

Iron Trade.—The expansion of the iron trade is one of the most remarkable things in the history of our national industry. When charcoal was used for fuel; when there were no steam-engines to force in a blast; when the air employed for the blast was cold; and when there were neither rolling-mills nor shingling-hammers, a large production was impossible. Nor was there such a demand as would make even an approach to that which now exists; for iron bridges, iron ships, iron houses, iron roads, iron pontoons, iron cables, iron articles—from 'Great Easterns' down to shirt-buttons—are things of the present. It is supposed that in 1740, the produce of iron in Great Britain was about 17,000 tons. In 1750, a bill was brought into parliament, in the interest of iron-purchasers, for the importation of iron from the American colonies. This was opposed by the *tanners*, on grounds not very easy to guess *à priori*, but curiously illustrative of the spirit of protection. If, it was argued, colonial iron be admitted, English iron masters would be undersold; if so, some would be ruined and others would leave the trade; if so, many of the furnaces and forges would be put out of blast; if so, less wood would be used for fuel; if so, there would be less oak-bark in the market; and if so, the tanners might suffer from a deficiency of tan-material. Later in the century, however, when improvements and new appliances were numerous, it mattered little whether colonial iron was imported or not; seeing that the home produce would supply all demands. By 1788, the produce reached 68,000 tons; the weekly produce from the blast-furnaces averaged about 20 tons each. By 1796, the produce was 125,000 tons, and the weekly average per furnace 27 tons (taking the celebrated Dowlais works as an exemplar). Approximate estimates made at different times, set down the quantities of pig-iron made at 250,000 tons in 1806, 400,000 tons in 1820, and 690,000 tons in 1827; the average produce per furnace being raised in those same years to about 42, 62, and 70 tons per week, partly by the adoption of larger dimensions in the furnaces themselves, and partly by improved processes.

The introduction of the hot blast by Mr. Neilson in 1829 was shortly followed by a very remarkable extension of the manufacture. The produce of 1836 was about 1,000,000 tons, and the weekly average per furnace about 85 tons. The year 1839 was the first for which any trustworthy statistics were obtained, the estimates for previous years having been little more than guesses. Mr. Mushet, for that year, set down the number of blast-furnaces at 430, of which 377 were at work, producing about 1,250,000 tons in all. Of the furnaces in blast, 135 were in Wales, 188 in England, and 54 in Scotland; Wales had the largest yield per furnace, but England the largest total yield. Soon after this period the Scotch manufacturers made such an enormous extension of the trade, that they quite glutted the market. The large profits led to the building of new furnaces; the discovery of blackband in the Airdrie district increased the available store of cheap raw material; the hot-blast effected a saving in the coking of the fuel; and the Scotch banking system led to the advance of capital almost to a reckless extent. Hence the produce of pig-iron in Scotland, which had been only 37,000 tons in 1830, rose to 197,000 tons in 1839, and 276,000 in 1843. It was especially in 1841 that the Scotch makers glutted the market, at a time when the demand was not brisk; Staffordshire and South Wales suffered severely, for they could not manufacture at a profit, at the prices established by the Airdrie masters. The railway mania of 1844-5, however, revived the trade; the companies not only took all the railway-bars available, but called for so enormous a quantity that new furnaces were needed to supply it. In 1845. Scotland alone made 470,000 tons of iron, of which no less than 234,000 were shipped at the Clyde for England and elsewhere; in 1846 these numbers rose to 522,000 and 277,000 tons respectively. Advancing to the year of the Great Exhibition, we find that Scotland produced in 1851 the vast quantity of 803,000 tons; which was increased to 840,000 in 1853. It had by this time been discovered that Scotland could make raw or pig-iron at a cost only a little exceeding 2*l*. per ton; from 1848 to 1853, the market price varied from 2*l*. to 3*l*.; many of the furnaces being thrown out of blast in the season when the market price only reached, or barely reached, the cost of production. Bar-iron fluctuated much more considerably; for it differs more in quality, and has had a larger amount of labour bestowed upon it, than pig or crude iron; it was sometimes as low as 5*l*. per ton, sometimes as high as 10*l*. Mr. Braithwaite Poole gave an estimate of the iron produce of 1852, for the whole kingdom; from which it appears that there were 497 furnaces in blast, 158 out of blast, and nearly 2,700,000 tons of iron produced—of which England produced 1,190,000, Scotland, 775,000, and Wales 716,000. The authority for this estimate was, however, not given; and so far as Scotland is concerned, it falls short of one given by Mr. Scrivenor.

The most trustworthy statistics of the iron trade of Great Britain, and the latest available in date, are probably those of Mr. Truran, published in his volume on the 'Iron Manufacture.' This engineer was manager of Guest's vast establishment at Dowlais, and afterwards of Crawshay's at Hirwain; and consequently had the best means of acquiring a practical knowledge of the whole subject. His figures refer to 1855. He gives the name of every iron-work in Great Britain; the number of blast-furnaces at each; the weekly power of production at each furnace; and the aggregate power of produce in the year. Avoiding all the minute detail, some of the more general results may be given here, dividing the island into districts for facility of comparison:—

Districts.	No. of Iron Works.	No. of Furnaces.	Weekly Average. tons.	Total Produce. tons.
South Wales	38	169	118	1,042,776
South Wales (anthracite)	11	37	72	139,880
North Wales	9	19	63	62,180
Dean Forest	5	10	94	48,880
Lancashire (charcoal)	4	4	?	4,200
South Staffordshire	65	169	108	950,520
North Staffordshire	7	19	104	102,960
Derbyshire	12	30	101	158,080
Shropshire	14	34	86	151,720
South and West Yorkshire	12	31	72	116,480
North Yorkshire and Durham	23	79	132	541,320
Scotland	37	145	145	1,082,640

These figures present much which is worthy of notice. The total producing power in 1855 was about 4,400,000 tons, made in 746 blast furnaces at 227 iron works; presenting an average weekly producing power of 113 tons per furnace. The shares of produce were, in round numbers, England 2,080,000; Wales 1,240,000; Scotland 1,080,000. In the South Wales district, the great Dowlais Works alone figure for 18 blast furnaces and a produce of 108,000 tons. The South Staffordshire district had numerous works, but none very large, the highest comprising five furnaces; the weekly yield varied from 80 to 150 tons per furnace. The Scotch works comprised many of large extent, such as the Gartsherrie with 16 furnaces, and the Dundyvan and Monkland with 9 each; the produce was very high, for none of the furnaces figured for less per week than 120 tons, and the average rose to 145. The most surprising advance, between 1839 and 1855, had been made in the Tees district, or Durham and North Yorkshire, owing to the discovery of ironstone in the Cleveland hills. This district had only 5 furnaces, of 50 tons weekly yield each, in 1839; whereas it had 79 furnaces, of 132 tons yield, in 1855. The largest or most powerful furnaces were in Monmouthshire (belonging to the so-called South Wales iron district), where some of them had a yield of more than 200 tons per week.

Mr. Truran was careful to state that the above were the producing *powers* of all our iron works, if all the furnaces had been in full blast throughout the whole year. But this is never the case; there are always many furnaces out of blast, and many periods of slackened operations. He selected the preceding year, 1854, to show actual instead of potential results; and he found them as follows:—

1854.	
Furnaces in blast	599
Weekly average per furnace	118 tons
Pig-iron manufactured	3,585,906 ,,

In the 16 years from 1839 to 1854, the furnaces in blast had increased from 379 to 599; the weekly average produce per furnace from 63 to 118 tons; and the total produce from (about) 1,250,000 tons to 3,590,000 tons—very nearly three-fold. To produce these 3,590,000 tons, Mr. Truran estimates that there were required

Clay ironstone	7,366,000 tons
Carboniferous ironstone	3,845,000 ,,
Siliceous ironstone	580,000 ,,
Hæmatite ironstone	555,000 ,,
Limestone as a flux	2,450,000 ,,
Coal as fuel	20,046,000 ,,
	34,842,000

Or, nearly 10 tons of crude material to make 1 ton of iron; but there seems to be included here, not only the coal for actual smelting, but also that for refining, casting, forging, &c. Almost as much coal is needed for converting pig-iron into malleable as for smelting from the ore. It is necessary to bear in mind that, for this same year 1854, Mr. Blackwell gave an estimate much below Mr. Truran's in the quantity of iron made, and still further below in the quantity of coal used; but the grounds for his estimate were not so fully stated. Mr. Blackwell allows 3 tons of coal for smelting 1 ton of iron, and 3 tons for converting 1 ton of pig iron into malleable.

Mention has more than once been made, in the foregoing paragraphs, of the vast Dowlais Works. No better example could be selected to illustrate the general character of all such establishments. More than a hundred years ago, the Earl of Windsor granted a lease of a portion of ground near (what was at that time) the small agricultural village of Merthyr Tydvil, on the confines of the counties of Glamorgan, Monmouth, and Brecknock; with a right to use the coal, iron, and limestone found beneath the surface. On this ground was erected a blast-furnace, which became the pattern or model for many others. On account partly of the smallness of the furnace, but still more of the imperfection of the smelting operations, the weekly yield of pig-iron per furnace was small. Forty years after the establishment of the works it was only 20 tons; by the year 1800 it had risen to 36; and taking successive intervals of ten years, it appears that the weekly yield per furnace was 50 tons in 1810, 62 in 1820, 78 in 1830, 88 in 1840, 102 in 1850; while the details already given show how probable it is that the yield will be vastly greater in 1860. Not only did the yield per furnace increase in this way, but the number of furnaces also underwent many augmentations. At the beginning of the present century there were 3, 4 in 1815, 8 in 1820, 12 in 1826, 18 at present; these being all *blast*-furnaces, irrespective of a much greater number of calcining, puddling, refining, founding, and other furnaces. Very early in the operations a Mr. Guest was one of the partners; and in the course of time his successors became sole owners of the vast property. The late Sir John Guest was a remarkable man: he learned practically all the operations of iron-making, from beginning to end; he made himself acquainted with the Welsh language, in order to become intimate with his work-people; and even when he possessed a residence of almost feudal magnificence at Morlais Castle, and had married a peer's daughter, his heart was still among the smoke and din of the works. Dowlais made 10,000 tons of pig-iron in 1810; whereas, in 1849, it made 100,000 tons. In 1852 it was calculated that the various furnaces and operations employed 5000 horse-power of steam-engines; that there were raised 2,000,000 tons of minerals from the ground beneath the estate, of which 800,000 tons consisted of ironstone, limestone, and coal, actually thrown into the furnaces; that *a ship a day* was freighted at Cardiff, on an average, with iron brought down from Dowlais by the Taff Vale railway and the Glamorganshire canal; that 10,000*l.* a week was paid in wages, the mere procuring of which by the appointed day, in coin, was a financial operation of no small magnitude; and that 7000 persons were employed at direct pay, who of course supported many thousands more at home. Some of the machinery is of the largest kind ever employed in iron-works. In 1857 there was a steam-engine powerful enough to blow the blast for six of the greatest furnaces; it had a beam of 40 tons, and a fly-wheel of 35 tons. The rolling-mill had a fly-wheel 21 feet in diameter, and a driving-wheel still larger. The rail-mill was capable of making 1000 tons of railway bars per week. Ever since the rise of the railway system, Dowlais has been famed for its railway bars more than for its castings; when it made 100,000 tons of iron per annum, three-fourths were sent from the works in the form of bars and rails. It is at night that the works should be seen, when all the furnaces are vomiting forth their flames high into the air, throwing around a lurid smoky light of extraordinary character. Most of the blast-furnaces are ranged in a semicircle, on the outside of which have gradually accumulated millions of tons of slag and rubbish; this slag, hot within long after it has become cool on the outside, occasionally cracks, and exhibits waving lines of red fire, bearing more resemblance to a volcano than anything else to be seen in this country. These vast heaps of rubbish are gradually filling up valleys, for there is no where else to place them; and portions of the upper section of the Taff Vale railway are laid on the slag itself, smoothed and graduated for the purpose. Within the works, noise, smoke, and heat are the three characteristics which overbear all others, and which leave an impression on the mind of a visitor not readily effaced.

IRON BOATS AND SHIPS. [SHIP-BUILDING.]

IRON BRIDGES. [BRIDGES.]

IRONY (εἰρωνεία), a refined species of ridicule, which under the guise of earnestness and simplicity exposes all undue pretensions, even while it professes to honour and admit them. It stands intermediate between naiveté, or frank simplicity, on the one hand, and banter and persiflage, on the other. From the former it is distinguished by the consciousness and intention of ridicule, which object again is more covert and less transparent in irony than in the latter. By Aristotle the ironical is opposed to the boastful (τῷ ἀλάζονι), and as a middle term between *the two* he places the truthful (τὸν ἀληθῆ). The Latins translated the word irony by "dissimulatio,' which however Quintilian (lib. ix., c. 2) disapproves of as very inadequate, and preferred the original, for which we are indebted to the refinement of the Athenians, among whom Socrates, the master in this art, was called emphatically the Ironical (ὁ εἴρων). The strict etymology of the term is very doubtful. One explanation, looking to the so-called Socratic method of question and answer, takes it to mean simply "the interrogator;" while another would derive it from εἴρειν, to fasten, which may have had reference to the skill wherewith Socrates reduced the sophists to the necessity of adopting some fixed and stable point for discussion, instead of loose and slippery declamation, which, as more favourable to delusion and fallacy, they preferred. Both explanations equally leave out of consideration that element of latent mockery which predominates in the modern acceptation of the word, but which was probably only accessory to the original idea. For while the serious object of the Socratic irony, in which he represented himself as desirous to learn of those whose claim to wisdom he laboured to expose, was to awaken reflection by the development of the consciousness, he nevertheless combined with it all the Attic urbanity and wit. It was consequently of two kinds, a finer and a grosser, according as he had to do with the more presumptuous arrogance of the sophists, whose undue and pernicious reputation he sought to subvert, or with those younger but not less conceited spirits, who yet sought his society for the sake of benefit and improvement, and therefore required a milder and more merciful treatment.

The ironical argument proceeds in simulated ignorance, and by appearing to agree with those whom its purpose is to refute, in holding certain erroneous opinions and maxims, brings out the antagonism of truth to error, and gradually involves them in inextricable difficulties. On this account it has been considered a species of apogogical argument (τῆς εἰς ἀδύνατον ἀπαγωγῆς), or reductio ad absurdum.

As a figure of rhetoric, it is correctly defined to be that mode in which our words convey a sense directly contrary to what we express, but agreeable to what we mean and are understood to mean. (Beattie, 'Moral Science,' c. i. § 1, p. 4.) In an opposite and somewhat extended sense those mistakes have been called ironical wherein our intended expressions receive an inverted signification.

Since the essence of irony consists in its serious and seeming simplicity, it is essential to its successful application that it should advance gradually to its ultimate object of exposure, and neither lose its covert character by rising too suddenly to exaggeration and extremes, nor yet so closely veil itself but that the intention of ridicule may appear through the assumed mask of earnestness and simplicity.

Of English writers Swift contains the strongest and the most numerous examples of irony.

IROQUOIS. [NORTH AMERICAN INDIANS.]

IRRADIATION denotes, properly, the emission of rays from a luminous object, but the word is generally used to signify an apparent enlargement of the disc of a celestial body: this enlargement being caused either by a deviation of the rays of light from a rectilinear direction, or by some illusion arising from the action of light on the eye.

When rays of light from points at the surface of an object fall on the retina, there may be produced on the latter an agitation extending within short distances about the points to which the rays in the pencils are made to converge by the humours of the eye: hence there may arise a perception of a fringe or border about a luminous body, and consequently an apparent enlargement of such body. Thus, the image of a star, when seen by the eye, appears to be a disc of sensible magnitude, instead of a mere point; which, on account of its remoteness, would be the case if the rays of each pencil produced no effect beyond their mathematical point of convergence: the disc of the sun or of the moon is conceived to be, in like manner, apparently enlarged; and thus, also, the part of the moon which, when the latter is new, is enlightened by the sun, appears to be a portion of a sphere of greater diameter than the part which is more faintly enlightened by the rays reflected from the earth.

A species of irradiation is caused by the blending together, upon the retina, of the circles of light produced by the pencils which fall upon it either before or after the rays in each have converged to a point; the humours of the eye not permitting that convergence to take place exactly on the membrane. A similar effect may be produced, to a greater or less degree, in a telescope, in consequence of defects in the object-glass, the irrationality of dispersion [DISPERSION], and diffraction, from all which the image of a luminous point is not a mere point, but has an apparent magnitude.

Before the invention of telescopes, the apparent magnitudes of celestial bodies were very erroneously estimated: thus, Tycho Brahé made the diameter of Venus twelve times and Kepler made it seven times as great as it is now known to be. Telescopes do not entirely remove the cause of such error, but, by increasing the diameters under which the bodies are seen, without at the same time magnifying the effect of irradiation, the error in the estimation of their apparent magnitudes is proportionally diminished.

It is a consequence of irradiation, that objects which are in reality of equal magnitudes appear frequently to differ in size according to their colour or to the quantity of light which falls upon them. Sir William Herschel remarked ('Phil. Trans.,' 1783) that when a bright circle was viewed together with a dark one on a bright ground, the latter always appeared smaller than the other; and, in order to correct the erroneous estimate of the magnitudes of the columns about temples when they are seen against a bright ground, it appears that the ancients made the thickness of the columns to increase proportionally to the distance between them. The reason assigned for this practice by Vitruvius ('De Architectura,' lib. 3, cap. 2) is, that the columns with wide intervals, being more surrounded by the air than those which are closer, appear on that account to be more slender. It must be observed, however, that the perceptions of magnitude depend partly on those of distance; and a contrary effect frequently takes place with objects viewed against the sky when conceived to be more remote than they really are.

IRRATIONAL QUANTITY. The distinction between quantity in general and number, or rather between the ratio of quantity to quantity, and that of number to number, has begun to appear in the article INCOMMENSURABLE, of which the present may be taken as a continuation. It there appears that there are such things as magnitudes which are not in the proportion of any one number to any other; though, if we may use numbers as great as we please, we can find a pair which shall be as nearly as we please in the ratio of any two given incommensurable quantities.

According to the modern use of the term irrational, it simply means not expressible by a finite fraction. The word *ratio*, or its equivalent *λόγος*, does not here mean reason, in the common sense of the word, but mathematical proportion. A quantity whose ratio to the unit of quantity cannot be expressed arithmetically, that is, by a whole number or a fraction, is "inexpressible by an arithmetical ratio," or "arithmetically irrational," abbreviated into "irrational." This explanation is very important, since the student might otherwise be led to suppose that irrational meant unreasonable, or absurd. Looking at the manner in which the common meaning of the word irrational is fixed in our minds, it would be well if the mathematical word were connected with its cognate *ratio*, by being pronounced irrational. Suppose for example that we have a geometrical problem which we solve by the application of arithmetic, taking a certain line to be unity, and applying the fundamental principles explained in RECTANGLE. Suppose the problem thus reducible to the solution of $x^2=2$, or the quantity sought is such a fraction as multiplied by itself will give 2. The arithmetical answer is very simple; there is no such fraction. But is the problem therefore impossible? By no means; for the line required must be the diagonal of a square whose side is the linear unit. What then is the reason for our not being able to produce an arithmetical solution? Because the ratio of the line sought to the linear unit given is not to be expressed arithmetically, or is in the preceding sense irrational. The student has now arrived at the point where he must be taught (if he have not learnt it before) that common arithmetic is not the science of all ratios or relative magnitudes, but only of the ratios or relative magnitudes of those quantities which are made by putting together quantities which are all equal to one another. The senses alone would never make this distinction, and those who desire nothing more than sensible evidence in their mathematical studies need not attend to it: unfortunately the present bent of such pursuits tends to inexactness, not explicitly avowed, but wearing the appearance of absolute rigour.

The student who begins to extract the square root of numbers is allowed to place the symbol of that process over numbers which do not admit of its performance, as $\sqrt{2}$, $\sqrt{3}$, &c. These symbols are reasoned on as if they represented fractions, and arithmetical deductions are drawn; but when it is required to reduce them to practice, then the possibility of determining their arithmetical values is denied, and it is implied that they have an existence which can only be approximately represented. Thus, since 1·4142 multiplied by itself gives 2 very nearly, it is said that 1·4142 is very nearly the square root of 2. This method, which is indispensably necessary in practice, should not be allowed in perfectly strict reasoning. It cannot be just to say that 2 has no square root, but that since fractions very near to 2 have square roots, therefore these square roots are very near to the non-existent square root of 2. It is only in a properly extended arithmetic, which by express agreement admits of extended symbols of ratio, that it can be lawful to speak of the square root of 2. [RATIO.] Waiving this point for the present, we proceed to further considerations, confining ourselves to those irrational quantities which arise from taking the square roots of numbers, but premising that similar remarks might be made on cube, fourth, &c., roots. If we take the series of numbers 1, 2, 3, &c., and extract the square root of each, we thereby obtain (1.) the original series 1, 2, 3, &c., by means of $\sqrt{1}$, $\sqrt{4}$, $\sqrt{9}$, &c.; (2.) a series of multiples of $\sqrt{2}$, namely, $\sqrt{2}$, $\sqrt{8}$, $\sqrt{18}$, &c., which are $\sqrt{2}$, $2\sqrt{2}$, $3\sqrt{2}$, &c.; (3.) a similar series of multiples of $\sqrt{3}$; and so on ad infinitum. The primitive numbers are either prime numbers or products of *different* prime numbers. Thus we have a series of multiples of $\sqrt{(7\times 5)}$, but not of $\sqrt{(7\times 7\times 5)}$, since this last is $7\sqrt{5}$, and, with its multiples, is included in those of $\sqrt{5}$. Any two quantities in the same series are commensurables; thus $7\sqrt{10}$ and $12\sqrt{10}$ are in the proportion of 7 to 10, and have $\sqrt{10}$ for a common measure: but any two which are in different series are incommensurables; thus $\sqrt{10}$ and $\sqrt{11}$ have no common measure whatsoever. And the sum or difference of any two incommensurable quantities is incommensurable with either; thus we can form infinite sets of binomials, such as $\sqrt{2}+\sqrt{3}$, $\sqrt{10}+\sqrt{11}$, $\sqrt{19}-\sqrt{5}$, &c., no one of which shall be commensurable with any other.

The square root of any arithmetical fraction is commensurable with that of the product of its numerator and denominator: thus $\sqrt{(\frac{3}{5})}$ is $\frac{1}{5}\sqrt{15}$. And the reciprocal of any square root is commensurable with that square root: thus $1\div\sqrt{7}$ is $\frac{1}{7}\sqrt{7}$. Also the fraction made by any two of the binomials just described is commensurable with the product of some similar pair: thus

$$\frac{\sqrt{3}+\sqrt{5}}{\sqrt{10}-2}=\tfrac{1}{6}(\sqrt{3}+\sqrt{5})(\sqrt{10}+2).$$

If we take the square root of one of the preceding binomials, a $\sqrt{(\sqrt{3}+\sqrt{5})}$ we have a new quantity, not commensurable with any of those just mentioned, except only in certain cases pointed out by the following theorem. Let a and b be two numbers, of which a is the greater:—

$$\sqrt{(\sqrt{a}\pm\sqrt{b})}=$$
$$\sqrt{\left(\frac{\sqrt{a}+\sqrt{(a-b)}}{2}\right)}\mp\sqrt{\left(\frac{\sqrt{a}-\sqrt{(a-b)}}{2}\right)}$$

If a and $a-b$ be both square numbers, let $a=p^2$, $a-b=q^2$, and we have

$$\sqrt{(\sqrt{a}\pm b)}=\tfrac{1}{2}\sqrt{(2p+2q)}\pm\tfrac{1}{2}\sqrt{(2p-2q)}.$$

Though Euclid was not acquainted with any direct algebraical process, yet he carried the distinction of incommensurable quantities to the length of a complete subdivision of all the possible cases which can be contained in the formula $\sqrt{(\sqrt{a}\pm\sqrt{b})}$. We are induced to give an account of his tenth book, because there does not, to our knowledge, exist any such thing in a form accessible to the student. Indeed, we do not know where to find a description of its details in any form whatsoever. In old geometrical writings references to the classification of this book are not unfrequently met with. If we take any given line to represent the unit of length, and if a, b, c, &c., represent lines commensurable with this unit, arithmetically expressed, it is well known that the most common geometry shows how to find the lines expressed by $\sqrt{a}$, $\sqrt{b}$, &c. All such lines Euclid terms rational, all others irrational (*ῥητος* and *ἄλογος*); and any area which being formed into a square has a rational side, he calls a rational area; that is, in fact, any area which is commensurable (*σύμμετρος*) with the square unit is rational. The term for the square on a line is its *power* (*δύναμις*), and from this comes the algebraical use of the word power. Thus, when he says that two lines are only commensurable in power, he means that the squares on them are commensurable, but not the lines themselves. A mean, or medial line (*μέσος*), is the mean proportional between two incommensurable rational lines, and is such as can be represented in algebra by $\sqrt[4]{a}$, where a is commensurable with the unit; and a medial area is the mean proportional between two rational areas, and its number of square units may be represented by $\sqrt{a}$.

A line which is made by putting together (*σύνθεσις*) two incommensurable rational lines is called a line of two names (*ἐκ δύο ὀνομάτων*), or a binomial line; while one which is made by taking away (*ἀφαίρεσις*) the lesser of two incommensurable rational lines from the greater is called an apotomé (*ἀποτομή*), literally, off-cut. The binomial therefore has one of the forms $a+\sqrt{b}$, and $\sqrt{a}+\sqrt{b}$, while the apotomé has one of the forms $\sqrt{a}-\sqrt{b}$, $a-\sqrt{b}$, $\sqrt{b}-a$. Six distinct species of each sort of line are found, and in connection with each set of six is another similar set, which a modern mathematician would describe as composed of the square roots of the first set. But Euclid describes the square roots as we should call them, previously to the lines themselves; and in order to render this article more available to those who look through the tenth book, we shall do the same. The whole amounts to this: that, taking a given line as the unit and standard, Euclid separates the lines represented by $\sqrt{(\sqrt{a}\pm\sqrt{b})}$, where a and b are commensurable with the standard unit, into twenty-five distinct classes, no one of which contains any lines commensurable with those of any other class. The following enumeration contains the order in which they make their appearance: a, b, &c., representing lines commensurable with the standard unit; A, B, C, D, E, F, the six binomial lines: $\sqrt{A}$, $\sqrt{B}$, &c., those connected with them: U, V, W, X, Y, Z, the six apotomæ: $\sqrt{U}$, $\sqrt{V}$, &c., those connected with them.

It is, however, to be noticed, that Euclid does not use the term unit, but supposes a rational line, to which he makes reference. Thus when he mentions in one place a rational line and a fourth binomial, he means that the fourth binomial shall be related to that rational line in the same manner as our following definition will connect it with the modern phrase, the standard unit.

(1). a, b, &c., lines commensurable with the unit.

(2). $\sqrt{a}$, $\sqrt{b}$, &c., lines commensurable in power with the unit. These two heads include the rational lines.

(3). $\sqrt[4]{a}$, $\sqrt[4]{b}$, &c., medial lines, described by Euclid as lines equal in power to the rectangle of incommensurable rational lines.

( ). $\sqrt{A}$ has the form $\sqrt{a}+\sqrt{b}$. A binomial line generally. This case contains all the six hereafter described and numbered, for which reason the numbering is here left blank. There is a proposition which we should now enunciate by saying that the square root of a binomial of the first species (A) is one or other, and may be either, of the six binomials.

(4). $\sqrt{B}$ has the form $(\sqrt{a}+\sqrt{b})\sqrt[4]{x}$, where abx is a square number. It is the first species of line composed of two medials, or a first bi-medial, and is compounded of two medials, which make a rational rectangle (*εὐθεῖα ἐκ δύο μέσων πρώτη*).

(5). $\sqrt{C}$ has the form $(\sqrt{a}+\sqrt{b})\sqrt[4]{x}$, where abx is not a square number. It is the second species of line composed of two medials, or a second bi-medial, and is compounded of two medial lines, which make a medial rectangle (*εὐθεῖα ἐκ δύο μέσων δευτέρα*).

(6). $\sqrt{D}$ has the form $\sqrt{(a+\sqrt{b})}+\sqrt{(a-\sqrt{b})}$, where a^2-b is not a square. It is described by Euclid as composed of two straight lines, incommensurable in power, whose squares together make a rational space, but whose rectangle is a medial space, and is called by him a greater line (*εὐθεῖα μείζων*).

(7). $\sqrt{E}$ has the form $\sqrt{(\sqrt{a}+\sqrt{b})}+\sqrt{(\sqrt{a}-\sqrt{b})}$, where $a-b$ is a square. It is described by Euclid as composed of two straight lines incommensurable in power, whose squares together make a medial space, but whose rectangle is a rational space; and it is called by him "a line in power making a rational and a medial space" (*εὐθεῖα ῥητὸν καὶ μέσον δυναμένη*). The nomenclature is not here quite correct, for the preceding line, called a greater line, is also a line in power equal to a rational and medial space.

(8). $\sqrt{F}$ has the form $\sqrt{(\sqrt{a}+\sqrt{b})}+\sqrt{(\sqrt{a}-\sqrt{b})}$, where $a-b$ is not square. It is described by Euclid as composed of two lines incommensurable in power, making both the sum of their squares and their rectangle medial spaces incommensurable with one another; and it is called "a line in power equal to two medial spaces" (*εὐθεῖα δύο μέσα δυναμένη*).

We now come to the description of the six binomial lines themselves.

(9). A has the form $a+b+2\sqrt{(ab)}$. It is described by Euclid as having the greater term commensurable with the standard unit, and more in power than the less by the square of a line commensurable with itself in length; and it is called the first binomial line (*εὐθεῖα ἐκ δύο ὀνομάτων πρώτη*).

(10). B has the form $(a+b+2\sqrt{(ab)})\sqrt{x}$, √where abx is a square. It is described as differing from the first binomial only in having the lesser term commensurable with the standard unit; and is the second binomial line.

(11). C has the form $(a+b+2\sqrt{(ab)})\sqrt{x}$, where abx is not a square. It differs from the two preceding only in neither term being commensurable with the standard unit.

In the first three binomial lines, reduced to the form $\sqrt{p}+\sqrt{q}$, $\sqrt{(p-q)}$ is commensurable with $\sqrt{p}$, the greater term: in the last three these two are incommensurable.

(12). D has the form $a+\sqrt{b}$, where a is greater than $\sqrt{b}$, and a^2-b is not a square. Euclid describes it as having the greater term more in power than the less by the square of a line incommensurable to itself in length, the same greater term being commensurable with the standard unit: it is the fourth binomial line.

(13). E has the form $a+\sqrt{b}$, where $\sqrt{b}$ is greater than a, and $b-a^2$ is not a square. It is described as differing from the preceding by having the less term commensurable with the standard unit: it is the fifth binomial line.

(14). F has the form $\sqrt{a}+\sqrt{b}$, where $a-b$ is not a square. It is described as differing from the two preceding by neither term being commensurable with the standard unit; and is the sixth binomial line.

We now come to the lines derived from the apotomæ, and afterwards to the apotomæ themselves. The descriptions might be shortened by allusion to the corresponding binomial lines, but this would impede the speedy reference to the complete meaning of any one term.

( ). $\sqrt{U}$ has the form $\sqrt{a}-\sqrt{b}$. An apotomé generally. The numbering is left blank, as this class of lines is afterwards subdivided. A proposition is proved, which we should now enunciate by saying hat the square root of an apotomé of the first kind is one or other, and may be any of the six apotomæ.

(15). $\sqrt{V}$ has the form $(\sqrt{a}-\sqrt{b})\sqrt[4]{x}$ where abx is a square. Euclid describes it as the difference of two medial lines which are commensurable in power, and whose rectangle is a rational space. He calls it the first kind of apotomé of a medial line (*μέσης ἀποτομὴ πρώτη*).

(16). $\sqrt{W}$ has the form $(\sqrt{a}-\sqrt{b})\sqrt[4]{x}$, where abx is not a square. It is described as differing from the former only in the medial lines containing a medial space, and is the second apotomé of a medial line.

(17). $\sqrt{X}$ has the form $\sqrt{(a+\sqrt{b})}-\sqrt{(a-\sqrt{b})}$ where a^2-b is not a square. Euclid describes it as the difference of two straight lines incommensurable in power, the sum of whose squares is rational, and their rectangle medial: and he calls it a lesser line (*εὐθεῖα ἐλάσσων*).

(18). $\sqrt{Y}$ has the form $\sqrt{(\sqrt{a}+\sqrt{b})}-\sqrt{(\sqrt{a}-\sqrt{b})}$ where $a-b$ is a square. It is described as the preceding, except that the sum of the squares is medial, and the rectangle rational: and Euclid calls it "a line which with a rational space makes a medial space" (*εὐθεῖα μετὰ ῥητοῦ μέσον τὸ ὅλον ποιοῦσα*) meaning that a certain rational space added to the square on it makes a whole space which is medial. There is not here the defect of nomenclature mentioned in (7), for the preceding line here can only be called "a line which with a medial space makes a rational space."

(19). $\sqrt{Z}$ has the form $\sqrt{(\sqrt{a}+\sqrt{b})}-\sqrt{(\sqrt{a}-\sqrt{b})}$ where $a-b$ is not a square. It is described by Euclid as the difference of two lines incommensurable in power, having the sum of their squares and their rectangle both medial: and it is called "a line which with a medial space makes a medial space" (*εὐθεῖα μετὰ μέσου μέσον τὸ ὅλον ποιοῦσα*).

The six apotomæ now follow, all in the form $\sqrt{a}-\sqrt{b}$; in the first three $\sqrt{(a-b)}$ is commensurable with $\sqrt{a}$, in the second three, incommensurable. And $\sqrt{a}$ is called the whole, but $\sqrt{b}$ is called the fitted or adapted line.

(20). U has the form $a+b-2\sqrt{(ab)}$. The whole is commensurable with the standard unit, and exceeds the adapted line in power by the square of a line commensurable with itself. Euclid calls this a first apotomé.

(21). V has the form $(a+b-2\sqrt{(ab)})\sqrt{x}$ where abx is a square. Described as the preceding, except that only the adapted line is commensurable with the standard unit; and is the second apotomé.

(22). W has the form $(a+b-2\sqrt{(ab)})\sqrt{x}$, where abx is not a square. Here neither the whole nor the adapted line is commensurable with the standard unit; this is the third apotomé.

(23). X has the form $a-\sqrt{b}$ where a^2-b is not a square. Euclid describes it by saying that the whole is commensurable with the standard unit, and exceeds the adapted line in power by the square of a line incommensurable with itself; and calls it the fourth apotomé.

(24). Y has the form $\sqrt{b}-a$ where $b-a^2$ is not a square. Described as the last, excepting that only the adapted line is commensurable with the standard unit: it is the fifth apotomé.

(25). Z has the form $\sqrt{b}-\sqrt{a}$ where $b-a$ is not a square. It differs from the two preceding by neither term being commensurable with the standard unit: and is the sixth apotomé.

Besides obtaining this classification, Euclid proves, firstly, that every one of these species is distinct from every other, and that every line which is commensurable with a line of any one species is itself a line of the same species. He shows also how to find lines of every species in which he directly applies the theory of numbers obtained in the seventh, eighth, and ninth books. He also demonstrates that no straight line can belong to one species in two different ways: proving, for example, an equivalent to the following, that $\sqrt{a}+\sqrt{b}$, if the terms be incommensurable, cannot be equal to $\sqrt{x}+\sqrt{y}$, where x differs from a, and y from b: which he expresses thus:—"a binomial line is divided into its names (or terms) in one point only." He then proves that the lines which we have denoted by $\sqrt{A}$, $\sqrt{B}$, &c., are derived from A, B, &c., in the manner which justifies our notation. For instance, "if a space be contained by a rational and a fourth binomial line, the line equal in power to the space is the irrational line called a greater line." Now, c representing a rational line, a fourth binomial derived from it has the form $a+\sqrt{b}$ where a is commensurable with c, and greater than $\sqrt{b}$, and $\sqrt{(a^2-b)}$ is not commensurable with c. His proposition then amounts to this, that $\sqrt{(ca+c\sqrt{b})}$ has the form

$$\sqrt{(x+\sqrt{y})}+\sqrt{(x-\sqrt{y})}$$

where $2x$ is a rational space (or the number $2x$ commensurable with c^2), and x^2-y is an irrational space, or that number is incommensurable with c^2. This involves the algebraical proposition, that the square root of $ca+c\sqrt{b}$ is

$$\sqrt{\left\{\tfrac{1}{2}ca+\tfrac{1}{2}c\sqrt{(a^2-b)}\right\}}+\sqrt{\left\{\tfrac{1}{2}ca-\tfrac{1}{2}c\sqrt{(a^2-b)}\right\}};$$

and in showing the identity of the forms, Euclid arrives at the manner of deriving one from the other. He also shows, in two propositions, that the form $\sqrt{(a+\sqrt{b})}$ gives either a binomial line, or (4), (6), or (7) of the preceding enumeration, and that $\sqrt{(\sqrt{a}+\sqrt{b})}$ gives either (5) or (8). In three more he shows that $\sqrt{(a-\sqrt{b})}$ gives either an apotomé or (17) of the enumeration, that $\sqrt{(\sqrt{b}-a)}$ gives either (15) or (18), and that $\sqrt{(\sqrt{a}-\sqrt{b})}$ gives either (16) or (19). He further shows the equivalent of the following algebraical proposition:—

$$\frac{1}{\sqrt{a}-\sqrt{b}}=\frac{\sqrt{a}+\sqrt{b}}{a-b}$$

The preceding enumeration points to one of the most remarkable pages in the history of geometry. The question immediately arises, had Euclid any substitute for algebra? If not, how did he contrive to pick out, from among an infinite number of orders of incommensurable lines, the whole, and no more than the whole, of those which were necessary to a complete discussion of all lines represented by $\sqrt{(\sqrt{a} \pm \sqrt{b})}$, without one omission or one redundancy? He had the power of selection, for he himself has shown how to construct an infinite number of other species, and an algebraist could easily point out many more ways of adding to the subject, which could not have been beyond Euclid. If it be said that a particular class of geometrical questions, involving the preceding formula and that one only, pointed out the various cases, it may be answered that no such completeness appears in the thirteenth book, in which Euclid applies his theory of incommensurables. It is there proved that each of the segments of a line divided in extreme and mean ratio is an apotomé—that the side of an equilateral pentagon inscribed in a circle is, relatively to the radius, the irrational line called a lesser line, as is also the side of an icosahedron inscribed in a sphere—and that the side of a dodecahedron is an apotomé. The apotomé then and the lesser line are the only ones applied.

It seems probable that the distinction of commensurable and incommensurable, and even a notion of different species of incommensurables, was familiar to the geometer before Euclid wrote: and this may be inferred, almost with certainty, from what is said by Proclus. Had it been otherwise, we must suppose that the definitions of the fifth book would have been accompanied by some little account of their necessity, and also that the absolute determination of two incommensurable magnitudes would not have been postponed till the last proposition of the tenth book. But it is impossible to draw any very positive conclusion on this subject. Owing to the loss of Euclid's book on Fallacies [Geometry], we are probably left without those notions which he intended to be preliminary to the elements.

The most conspicuous propositions of elementary geometry which are applied in the tenth book are the 27th, 28th, and 29th of the sixth book, of which it may be useful to give the algebraical signification. The first of these (the 27th) amounts to showing that $2x-x^2$ has its greatest value when $x=1$, and contains a limitation necessary to the conditions of the two which follow. The 28th proposition is a solution of the equation $ax-x^2=b$, upon a condition derived from the preceding proposition, namely, that $\frac{1}{4}a^2$ shall exceed b. It might appear more correct to say that the solution of this equation is one particular case of the proposition, namely, where the given parallelogram is a square; but nevertheless the assertion applies equally to all cases. Euclid however did not detect the *two* solutions of the question; though if the diagonal of a parallelogram in his construction be produced to meet the production of a line which it does not cut, the second solution may be readily obtained. This is a strong presumption against his having anything like algebra; since it is almost impossible to imagine that the propositions of the tenth book, deduced from any algebra, however imperfect, could have been put together without the discovery of the second root. The remaining proposition (the 29th) is equivalent to a solution of $ax+x^2=b$: but the case of $x^2-ax=b$ is wanting, which is another argument against Euclid having known any algebraical reasoning.

IRREDUCIBLE CASE (that is, of cubic equations), the common name of a particular class of cubic equations, to which Cardan did not succeed in applying his celebrated rule. Bombelli however showed that the reason of this was the reality of all the three roots. The following is the sketch both of the method and the difficulty. [Bombelli; Cardan; Tartaglia, in Biog. Div. Theory of Equations; Negative and Impossible Quantities.]

Unity has three cube roots, 1, $-\frac{1}{2}(1-\sqrt{-3})$, and $-\frac{1}{2}(1+\sqrt{-3})$, of which the product of the second and third is possible and equal to unity. Calling these 1, r, and r', it is next shown that a^3 has three cube roots, namely, a, ra, and $r'a$. Now, let there be a cubic equation (A, B, and C being real quantities)

$$x^3+\mathrm{A}x^2+\mathrm{B}x+\mathrm{C}=0;$$

and, by the method explained in Involution and Evolution, find another equation which has each root greater than a root of the preceding by $\frac{1}{3}\mathrm{A}$. We have then

$$x^3+\mathrm{P}x+\mathrm{Q}=0 \quad . \; . \; . \quad (1)$$

$$\mathrm{P}=\mathrm{B}-\tfrac{1}{3}\mathrm{A}^2 \qquad\qquad \mathrm{Q}=\mathrm{C}-\tfrac{1}{3}\mathrm{AB}+\tfrac{2}{27}\mathrm{A}^3.$$

Let x be $v+w$: then $x^3=v^3+w^3+3vwx$, and (1) becomes

$$v^3+w^3+(3vw+\mathrm{P})\,x+\mathrm{Q}=0 \quad . \; . \quad (2).$$

Determine v and w so that

$$3vw+\mathrm{P}=0 \qquad\qquad v^3+w^3+\mathrm{Q}=0;$$

by which means (2), and therefore (1), is satisfied. This gives

$$v^3\ (\text{or } w^3)=-\tfrac{1}{2}\mathrm{Q}+\sqrt{(\tfrac{1}{4}\mathrm{Q}^2+\tfrac{1}{27}\mathrm{P}^3)}$$
$$w^3\ (\text{or } v^3)=-\tfrac{1}{2}\mathrm{Q}-\sqrt{(\tfrac{1}{4}\mathrm{Q}^2+\tfrac{1}{27}\mathrm{P}^3)},$$

from which v and w can be found. But as each of the two, v^3 and w^3, has three cube roots; and as no reason yet appears for choosing one rather than another, it should seem as if the possible combinations by which $v+w$ might be made would be nine in number. But on looking back we find the condition $3vw=-\mathrm{P}$; so that the product of v and w must be a possible quantity. And since nothing but P^3 appears in v and w, the same values of v and w would appear whatever cube root of P^3 might have appeared in the original equation: consequently the six values of $v+w$ which are now to be abandoned belong to the roots of $x^3+\mathrm{P}r\,x+\mathrm{Q}=0$, and $x^3+\mathrm{P}r'\,x+\mathrm{Q}=0$. If then we signify by v and w the real cube roots of v^3 and w^3, the others are rv and $r'v$, rw and $r'w$; and the only combinations which satisfy the condition $3vw+\mathrm{P}=0$ are

$$v+w,\ rv+r'w,\ r'v+rw,$$

which are the three roots of the equation (1): to the exclusion of $v+rw$, $rv+w$, $r'v+r'w$, the roots of $x^3+\mathrm{P}r\,x+\mathrm{Q}=0$; and $v+r'w$, $r'v+w$, $rv+rw$, the roots of $x^3+\mathrm{P}r'x+\mathrm{Q}=0$. So far all is right, and the algebraical solution is complete, and may be represented thus: let ρ stand for any cube root of unity; then the three solutions of (1) are contained in

$$\rho\sqrt[3]{\left\{-\tfrac{1}{2}\mathrm{Q}+\sqrt{(\tfrac{1}{4}\mathrm{Q}^2+\tfrac{1}{27}\mathrm{P}^3)}\right\}}$$
$$+\frac{1}{\rho}\sqrt[3]{\left\{-\tfrac{1}{2}\mathrm{Q}-\sqrt{(\tfrac{1}{4}\mathrm{Q}^2+\tfrac{1}{27}\mathrm{P}^3)}\right\}}$$

where $\sqrt[3]{\ }$ signifies the real cube root.

This is perfectly intelligible when $\frac{1}{4}\mathrm{Q}^2+\frac{1}{27}\mathrm{P}^3$ is a positive quantity: for if we call the real cube roots above mentioned K and L, we find for the three roots of the equation, first, the possible root, K + L; next, the pair of impossible roots contained in the formula

$$-\tfrac{1}{2}(\mathrm{K}+\mathrm{L}\pm\tfrac{1}{2}(\mathrm{K}-\mathrm{L})\sqrt{-3}.$$

If we apply this to the equation $x^3-9x-28=0$, where $\mathrm{P}=-9$, and $\mathrm{Q}=-28$, we shall find $\mathrm{K}=3$, $\mathrm{L}=1$, and the roots are $4, -2+\sqrt{-3}$, and $-2-\sqrt{-3}$. But if it should happen that $\frac{1}{4}\mathrm{Q}^2+\frac{1}{27}\mathrm{P}^3$ is negative (which requires that P should be negative and $\frac{1}{27}\mathrm{P}^3$ numerically greater than $\frac{1}{4}\mathrm{Q}^2$), we return to the original form of the solution, and find that the roots of the equation are contained in the formula

$$\left\{\mathrm{V}+\mathrm{W}\sqrt{-1}\right\}^{\frac{1}{3}}+\left\{\mathrm{V}-\mathrm{W}\sqrt{-1}\right\}^{\frac{1}{3}} \quad . \; . \; . \quad (3)$$

where $\left\{\quad\right\}^{\frac{1}{3}}$ means any cube root, there being a tacit condition that the product of the two cube roots must be possible. (V stands for $-\frac{1}{2}\mathrm{Q}$, and W for the possible (though perhaps irrational) quantity $\sqrt{(-\frac{1}{4}\mathrm{Q}^2-\frac{1}{27}\mathrm{P}^3)}$. Now it is shown in books of algebra that every cube root of $\mathrm{V}+\mathrm{W}\sqrt{-1}$ is of the same form, say $\mathrm{F}+\mathrm{G}\sqrt{-1}$, and that the corresponding cube root of $\mathrm{V}-\mathrm{W}\sqrt{-1}$ is $\mathrm{F}-\mathrm{G}\sqrt{-1}$. If, then, we assume

$$\left\{\mathrm{V}+\mathrm{W}\sqrt{-1}\right\}^{\frac{1}{3}}=\mathrm{F}+\mathrm{G}\sqrt{-1},$$
$$\left\{\mathrm{V}-\mathrm{W}\sqrt{-1}\right\}^{\frac{1}{3}}=\mathrm{F}-\mathrm{G}\sqrt{-1},$$

we find by multiplication

$$\left\{\mathrm{V}^2+\mathrm{W}^2\right\}^{\frac{1}{3}}=\mathrm{F}^2+\mathrm{G}^2;$$

and by addition of their cubes, and division by 2,

$$\mathrm{V}=\mathrm{F}^3-3\mathrm{FG}^2,$$

between which the elimination of G gives

$$\mathrm{F}^3-\tfrac{3}{4}\sqrt[3]{\mathrm{V}^2+\mathrm{W}^2}\,.\,\mathrm{F}-\tfrac{1}{4}\mathrm{V}=0;$$

from which it would seem that we might find F, and then G. But on examining this last equation we find it to be precisely that kind of cubic equation about which the difficulty arose; for the P of this equation is negative, being $-\frac{3}{4}\sqrt[3]{(\mathrm{V}^2+\mathrm{W}^2)}$, and the Q is $-\frac{1}{4}\mathrm{V}$; and $\frac{1}{27}\mathrm{P}^3$, being $-\frac{1}{64}(\mathrm{V}^2+\mathrm{W}^2)$, is numerically greater than $\frac{1}{4}\mathrm{Q}^2$, or $\frac{1}{64}\mathrm{V}^2$. Whence this case is called irreducible; for though, as will be shown immediately, there are three possible values of the expression (3), yet every direct algebraical attempt to find them leads to the same difficulty in another form.

If F and G could be determined, one value of (3) is 2 F; and taking the other cube roots, selecting only those pairs whose products are possible, we find

$$-\tfrac{1}{2}(1+\sqrt{-3})\,(\mathrm{F}+\mathrm{G}\sqrt{-1})-\tfrac{1}{2}(1-\sqrt{-3})\,(\mathrm{F}-\mathrm{G}\sqrt{-1})$$
$$-\tfrac{1}{2}(1-\sqrt{-3})\,(\mathrm{F}+\mathrm{G}\sqrt{-1})-\tfrac{1}{2}(1+\sqrt{-3})\,(\mathrm{F}-\mathrm{G}\sqrt{-1})$$

for the other admissible values. These may be reduced to

$$-\mathrm{F}+\mathrm{G}\sqrt{3}, \text{ and } -\mathrm{F}-\mathrm{G}\sqrt{3},$$

which are both possible. Consequently, the irreducible case of a cubic equation is that in which the three roots are all possible.

Let us apply the preceding to $x^3-21x+20=0$. Here $\mathrm{P}=-21$, $\mathrm{Q}=20$, $\frac{1}{4}\mathrm{Q}^2+\frac{1}{27}\mathrm{P}^3=-243=-81\times3$. Hence the roots are contained in

$$\left\{-10+9\sqrt{3}\sqrt{-1}\right\}^{\frac{1}{3}}+\left\{-10-9\sqrt{3}\sqrt{-1}\right\}^{\frac{1}{3}}.$$

By trial (or by semi-tentative methods, described in many older books of algebra) it may be found that a cube root of $-10+9\sqrt{3}\ \sqrt{-1}$ is $2+\sqrt{3}\ \sqrt{-1}$; whence $\text{F}=2$, $\text{G}=\sqrt{3}$. Hence one root (2F) is 4; the second and third ($-\text{F}+\text{G}\sqrt{3}$ and $-\text{F}-\text{G}\sqrt{3}$), are $-2+3$ and $-2-3$, or 1 and -5.

But the best method of obtaining the roots is by having recourse to a registry of the roots of cubic equations which is in the hands of every tyro, namely, the tables of sines and cosines, by which also the theorem of Bombelli will be established, namely, that the difficulty of the irreducible case answers to that of the trisection of an angle in geometry. It is proposed then, by means of trigonometry, to calculate the values of (3). Assume $\text{V}=r\cos.\theta$, $\text{W}=r\sin.\theta$, or find r and θ from

$$r=\sqrt{\text{V}^2+\text{W}^2},\qquad \tan.\theta=\frac{\text{W}}{\text{V}}$$

in which that sign must be given to r, which gives $r\cos.\theta$ the sign of V. Then, by De Moivre's theorem [NEGATIVE AND IMPOSSIBLE QUANTITIES],

$$(\cos.\theta\pm\sin.\theta\sqrt{-1})^{\frac{1}{3}}=\cos.\tfrac{1}{3}\theta\pm\sin.\tfrac{1}{3}\theta\sqrt{-1},$$

in which, by substituting $\theta+360°$ or $\theta+720°$ for θ, the equation $\tan.\theta=\text{V}\div\text{W}$ is still satisfied, and while the first side of the preceding equation is not altered in appearance, the different values of the cube root appear on the second side. From this we readily find that the expression (3) is no other than $2\sqrt[3]{r}\,.\cos.\frac{1}{3}\theta$; the three values of which, obtained as just noted, are

$$2\sqrt[3]{r}\,.\cos.\tfrac{1}{3}\theta,\ 2\sqrt[3]{r}\,.\cos.(120°+\tfrac{1}{3}\theta),\ 2\sqrt[3]{r}\,.\cos.240°+\tfrac{1}{3}\theta)$$

which may be thus written:—

$$2\sqrt[3]{r}\,.\cos.\tfrac{1}{3}\theta,-2\sqrt[3]{r}\,.\cos.(60°-\tfrac{1}{3}\theta),-2\sqrt[3]{r}\,.\cos.(60°+\tfrac{1}{3}\theta.)$$

Thus, in the preceding example, which gives $\text{V}=-10$, $\text{W}=9\sqrt{3}$, we find $r^2=100+243=343=7^3$; whence $\sqrt[3]{r}=-\sqrt{7}$. And $\tan.\theta=-\frac{9}{10}\sqrt{3}$, whence θ is found to be $-(57°\ 19'\ 16'')$, one-third of which is $-(19°\ 6'\ 25'')$, and this, with $79°\ 6'\ 25''$ and $40°\ 53'\ 35''$, are the angles on which the required values depend. The cosines of these angles, severally multiplied by $-2\sqrt{7}$, $2\sqrt{7}$, and $2\sqrt{7}$, give results as near to -5, 1, and 4 (the values found), as the unavoidable errors in the last places of logarithmic results, and the preceding rejection of fractions of seconds, will permit.

IRRIGATION. Of all the substances which concur in the vegetation and growth of plants water is the most essential; without moisture the seed cannot germinate, nor can the plant receive nourishment. Hence in warm climates, where rains are periodical, and where the soil is dried and parched by a continued evaporation, no verdure exists, except where springs or rivers supply the waste of moisture. The warmer the climate, and the more rapid the evaporation, the more luxuriant is the vegetation, provided there be an abundant supply of water. This circumstance has suggested the plan of diverting streams and conducting them in channels to fertilise as great an extent of land as possible. In China and in India, as well as in Egypt, ingenious modes of watering lands have been adopted from the most remote ages. No expense has been thought too great to secure a supply of water, and to distribute it in the most advantageous manner. It seems that where there is great heat in the air, water alone will supply the necessary food for the growth of plants. It is probable that the component parts of the atmosphere are more easily separated, and made to enter into new combinations with those of water, in a high temperature than in a lower; or that the leaves and green parts of vegetables imbibe water in a state of solution in air, and in this state it is more easily decomposed. Atmospheric air and water contain all the principal elements of vegetables, namely, oxygen, hydrogen, carbon, and nitrogen; the remainder are either found in the soil or diffused through the water.

Water has also an important office to perform, if we admit the principle discovered by Macaire, that plants reject through their roots those portions of the sap which are the residue of its elaboration, and which are of no further use to the plant, but rather injurious if they are again imbibed by the roots. Plants may perhaps require a removal of their excrements, as animals do when tied up in stalls, or confined in a small space; and the percolation of water through the soil may be the means which nature has provided for this purpose. Hence we can readily suppose that the mere washing of the roots has a beneficial effect, and to this in a great measure must be ascribed the fertilising effects of pure and soft running water. But besides this washing of roots, there is the constant feeding of them, which is the more probable explanation of the fertilising influence of that constant current of water among them which is produced in drained and in irrigated land.

If water stagnates and is evaporated, and the noxious matter held in solution remains in the soil, all the advantage of irrigation is lost, and the better kinds of grasses are succeeded by rushes and coarse aquatic plants, as may be seen in all marshy spots. The circulation of the water therefore appears to be as necessary as its presence; and, provided there be a sufficient supply of water of a proper quality, the more porous is the soil, and especially the subsoil, the more vigorous is the vegetation. It is on this principle alone that we can rationally account for the great advantage of irrigation in those climates where rain is abundant, and where the soil, which is most benefited by having a supply of water running through it, is of a nature to require artificial draining as an indispensable preliminary to being made fertile by irrigation. By keeping these principles in view great light will be thrown on the practical part of irrigation, which, having been long established by experience before these principles were thought of, depends not on their correctness, but only confirms their truth.

The whole art of irrigation may be deduced from two simple rules, which are, first, to give a sufficient supply of water during all the time the plants are growing, and secondly, never to allow it to accumulate so long as to stagnate. We shall see hereafter one apparent exception to this last rule, but it will be readily explained.

The supply of water must come from natural lakes and rivers, or from artificial wells and ponds, in which it is collected in sufficient quantity to disperse it over a certain surface. As the water must flow over the land, or in channels through it, the supply must be above the level of the land to be irrigated. This is generally the principal object to be considered. If no water can be conducted to a reservoir above the level of the land, it cannot be irrigated. But there must also be a ready exit for the water, and therefore the land must not be so low as the natural level of the common receptacle of the waters, whether it be a lake or the sea, to which they run. The taking of the level is therefore the first step towards an attempt to irrigate any lands.

Along the banks of running streams nature points out the declivity. A channel, which receives the water at a point higher than that to which the river flows, may be dug with a much smaller declivity than that of the bed of the river, and made to carry the water much higher than the natural banks. It may thence be distributed so as to descend slowly and water a considerable extent of ground in its way to rejoin the stream. This is by far the most common mode of irrigation; and the shape, size, and direction of the channels are regulated by the nature of the surface and other circumstances, which vary in almost every situation. A few examples will give to those who are not acquainted with the best modes of irrigating land a pretty accurate notion of the system.

We shall suppose a river to run with a rapid current between high banks. At some point of its course a portion of the water is diverted into a canal dug along the bank, with a very small declivity. The water in this canal will flow with less rapidity than the river, keeping nearly the same level as that part of the river where it has its origin. Thus the water may be carried over lands which are situated considerably above the bed of the river farther down. All the lands between this canal and the river may be irrigated if there is a sufficient supply of water. The canal may be carried to a considerable distance from the river. The size of the canal and its declivity depend on the quantity of water which may be made to flow into it. A dam is often constructed across a river, in order that as much of its water as is possible may be diverted, and the original channel is often laid quite dry, to take advantage of all the water at the time when it is advantageous to irrigate the land. To have an entire command of the water there are flood-gates on the main channel and on the lesser branches. By opening or shutting these the water may be stopped or made to flow as may be required. It must be remembered, that to carry water to a considerable distance, and in great quantity, a larger channel and more rapid declivity are required; and it is a matter of calculation whether it is most advantageous to bring a smaller quantity to a higher point, or a greater abundance somewhat lower. Having a certain command of water, it may be carried from the main channel by smaller branches to different points, so as to irrigate the whole equally. These branches should be nearly horizontal, that the water may overflow the sides of them, and be equally distributed over the land immediately below. Every branch which brings water over the land should have a corresponding channel below to carry it off; for the water must never be allowed to stop and stagnate. When it has run 15 or 20 feet, according to the declivity, over the land situated below the *feeder*, or the channel which brings the water, it should be collected into a drain to be carried off, unless it can be used to irrigate lands which lie still lower. Finally it runs back into the river from which it was taken, at a lower point of its course.

When there is a considerable fall and a sufficient supply of water, a series of channels may be made, so situated below each other, that the second collects the water which the first has supplied, and in its turn becomes a feeder to irrigate the lower parts of the declivity: a third channel receives the water and distributes it lower down, until the last pours it into the river. This is called *catch work*, because the water is caught from one channel to another. This method is only applicable where there is a considerable fall of water and a gentle declivity towards the river. But it must be borne in mind that the water is deteriorated for the purpose of irrigation, when it has passed over the land, and that it is not advantageous to let it flow over a great extent when a fresh supply can be obtained: but where only a small portion of water can be commanded, that must be made the most of; and it will irrigate three or four portions of land in succession without there being any very marked difference in the effect: beyond this it rapidly loses its fertilising qualities. This is not owing to the water having deposited the fertilising substances which it held in solution, or which were diffused through it, but to its having taken up some substances which are detrimental to vegetation, and being saturated with them: at least this is the most probable opinion when all circumstances are taken into the account.

The general principle of irrigation may be described as the supplying every portion of the surface with an abundance of water, and taking it off again rapidly. In many situations the great difficulty in irrigation arises from the want of a supply of water; but even then a partial irrigation may be effected, which, although not perfect, will have its advantages. A small rill which is often quite dry in summer may still, by judicious management, be made to improve a considerable portion of land: its waters may be collected and allowed to accumulate in a pond or reservoir, and let out occasionally, so that none be lost or run to waste. If there is but a small quantity it must be husbanded and made to flow over as great a surface as possible. If there is water only at particular seasons of the year, and at a time when it would not be of much use to the land, it may be kept in ponds, and it will lose none of its qualities by being exposed to the air. If animal or vegetable matter in a partial state of decomposition is added to this water, it will much improve its quality, and by a judicious distribution of it over the land a great benefit may be obtained.

If there is not a want of water, there may be a want of declivity to enable it to flow off, which, it should always be remembered, is an essential part of irrigation. Art may in this case assist nature by forming a passage for the water, either in its course towards the land to be irrigated, or from it after it has effected its purpose. Where there is no natural exit, and it might lead to too great an expense to make an artificial one, the water may sometimes be led into shallow ponds, where a great part is evaporated; or porous strata may be found by boring, into which it can be made to run and be dispersed. Along rivers where the fall is very imperceptible a channel brought from a considerable distance may give such a command as to throw the water over a great extent of surface; and to carry it off another channel may be cut, emptying itself at some distance below: so that lands which lie along the banks of a river may be irrigated, although they are actually below the level of the river, and require banks to protect them from inundation.

When the surface to be irrigated is very flat and nearly level, it is necessary to form artificial slopes for the water to run over. The whole of the ground is laid in broad beds, undulating like the waves of the sea. The upper part of these beds is quite level from end to end, and here the channel which brings the water is cut. From the edge of this channel the ground is made to slope a foot or two on both sides, and a ditch is cut at the bottom parallel to the float. The whole of the ground is laid out in these beds. All the supply furrows are fed by a main channel at right angles to the beds and somewhat above them, and all the ditches or drains run into a main ditch parallel to the main float, and below the lowest drain. The course of the water is very regular. As soon as the flood-gates are opened it flows into all the upper channels, which it fills till they overflow in their whole length. The sloping sides are covered with a thin sheet of running water, which the lower drains collect and carry into the main ditch.

Experience has shown that there are particular seasons when the water has the best effect; a perfect command of it is therefore indispensable, and also a regular supply. During frost, when all dry meadows are in a state of torpor, and the vegetation is suspended, the water-meadows, having a current of water continually flowing over them, are protected from the effect of frost, and the grass will continue to grow as long as the water flows over it. Too much moisture however would be injurious, and the meadows are therefore laid dry by shutting the flood-gates, whenever the temperature of the air is above freezing. By this management the grass grows rapidly at the first sign of spring. Before the dry upland meadows have recovered the effects of frost and begun to vegetate, the herbage of the water-meadows is already luxuriant. As soon as they are fed off or cut for the first crop of hay, the water is immediately put on again, but for a shorter time; for the warmer the air, the less time will the grass bear to be covered with water. A renewed growth soon appears, and the grass is ready to be cut a second time when the dry meadows only give their first crop. Thus, by judicious management, three or four crops of grass are obtained in each season, or only one abundant crop is made into hay, and the sheep and cattle feed off the others. The usual way in which the grass of water-meadows is made profitable is by feeding ewes which have early lambs till the middle of April. A short flooding soon reproduces a crop, which is mown for hay in June; another flooding gives an abundant aftermath, which is either mown for hay, or fed off by cows, bullocks, and horses; for at this time the sheep, if pastured in water-meadows, are very subject to the rot. The value of good water-meadows could scarcely be believed by those who are not familiar with them. Where the water is suited to irrigation they never require manuring. Their fertility is kept up continually, and the only attention required is to weed out coarse aquatic plants, which are neither nutritious nor wholesome in hay or pasture.

The best soil for a water-meadow is a good gravel. The finest water-meadows on the Avon in Wiltshire, where the richest herbage is found, have scarcely any soil at all, but are on little more than a bed of shingle matted together by the roots of the grass, which proves that the waters of the Avon contain all the principles essential to rapid vegetation. Great attention is required, and some experience, to irrigate meadows, so as to give the greatest profit.

In hot weather, when we should imagine that the land must be thirsty, and that too much water cannot be poured over it, much mischief may be done by injudicious flooding. In winter, on the contrary, the land may be covered with water for weeks without injury; and if an earthy deposit takes place, the subsequent fertility is greatly increased. But this is not properly irrigation: it is inundation, and the effects depend on entirely different causes. When low meadows are inundated in winter and spring, it is the muddiness of the water which enriches the land: a fine layer of extremely divided matter is deposited, and when the water subsides this acts as a coat of manure.

Water may be carried in small channels through meadows without being allowed to overflow, and in this case the effect is similar to that caused by rivers or brooks which wind slowly through valleys, and produce a rich verdure along their course. This is watering, but not properly irrigating. When this is done judiciously, the effect is very nearly the same as when the land is irrigated; and in hot climates it may be preferable, by giving a constant supply of moisture to the roots, while the plants are growing. The great advantage of water-meadows in England is not so much the superior quantity of grass or hay which is obtained when they are mown, as the early feed in spring, when all kinds of nutritive fodder are scarce. When the turnips are consumed before the natural grass or the rye sown for that purpose is fit to be fed off, the water-meadows afford abundant pasture to ewes and lambs, which by this means are brought to an early market. The farmer who has water-meadows can put his ewes earlier to the ram, without fear of wanting food for them and their lambs in March, which is the most trying season of the year for those who have sheep. At that time an acre of good grass may be worth as much for a month as a later crop would for the remainder of the year.

When it is intended to form a water-meadow on a nearly level surface, or where a fall of only two or three feet can be obtained in a considerable length, the whole of the land must be laid in beds about 20 or 30 feet wide, the middle or crown of these beds being on a level with the main feeders, and the bottoms or drains on a level with the lower exit of the water, or a little above it. To form these beds most expeditiously, if the ground is already in grass, the sod may be paired off and relaid after the beds are formed, by which means the grass will be sooner re-established; but except in very heavy soils, where the grass is some time in taking root, the easiest and cheapest way is to plough the land two or three times towards the centre, and dig out the drain with the spade: the earth out of the drains, and that which is taken out of the upper trench or feeder, may be spread over the bed to give it the proper slope. A roller passed over the bed in the direction of its length will lay it even, and the seeds of grass being sown over it, the water may be let on for a very short time to make them spring. As soon as the grass is two or three inches above ground a regular flooding may be given, and in a short time the sward will be complete. Instead of sowing seed, tufts of grass cut from old sward may be spread over the newly formed beds, and they will soon cover the ground. The Italian rye-grass, for instance, grows so rapidly, that if it be sown in February, or as soon as the snow and frost are gone, it will afford a good crop to feed off in April, or to mow for hay by the beginning of May; and after that it may be cut repeatedly during the summer. But where the soil is good and the water abundant, good natural grasses will spring up without much sowing, and soon equal the old water meadows.

It seems essential to the formation of a good water-meadow that the bottom be porous and free from stagnant water; hence underdraining is often indispensable before a water-meadow can be established: and a peat-bog, if drained and consolidated, may have water carried over its surface, and produce very good herbage. If the soil is a very stiff clay, draining is almost indispensable where a water-meadow is to be made. The more porous the soil the less depth of water is required, which is not obvious at first sight; but the clay lets the water run over the surface without soaking into the roots, whereas the porous soil is soon soaked to a considerable depth. The water must therefore be longer on the clay than on the sand or gravel to produce the same effect. If the water is properly applied all kinds of soils may be converted into fertile water-meadows. On very stiff clays a coat of sand or gravel, where it can be easily put on, will greatly improve the herbage. It should not be ploughed in, but laid on the surface two or three inches thick: chalk will also improve the herbage.

The usual time of letting on the water on water-meadows is just before Christmas, and it may continue to flow over the land as long as the frost lasts, unless the frost be very severe and the land be frozen: in mild weather it may be turned off during the day and put on again at night until the frost is gone. The grass will soon begin to grow, and be ready to be fed off. When this is done the water is immediately let on for a short time, and turned off again to allow the ground to dry after a few days' flooding, and the water is let on again at short intervals. The warmer the air is, the shorter time must the water be allowed to cover the meadows. As soon as the grass is five or six inches long it must be left dry entirely till it is mown or fed off.

In summer the floodings must be very short; seldom more than twenty-four hours at a time, but frequent. Thus a great weight of grass may be obtained year after year without any manure being put on the land, care being taken that where the surface is not quite even the hollows be filled up with earth brought from another place, or dug out of the drain, if that should be partially filled up with the soil which the water has carried into it. We alluded before to a case where water may remain a considerable time on the land without injury; this is, when there are inundations from rivers, which rise above their beds in spring and cover the low meadows which lie along their banks. In this case the grass, which has not yet sprung up, is protected from the cold, and if there be a deposit from the water there is a considerable advantage. But when it subsides, it must be made to run off entirely, without leaving small pools, by which the grass would inevitably be injured. Small ditches or channels are usually dug, by which all the water may run off, unless where the subsoil is very porous, or the land is well under-drained, which is seldom the case in these low meadows, for the drains would be apt to be choaked by the earthy deposit from the water. These inundations can sometimes be regulated by means of dykes and flood gates, in which case they partake of the advantages of irrigation, and also of that deposition of fertilising mud which is called warping. [WARPING.]

At a lecture given before the English Agricultural Society, at their Salisbury meeting, Mr. J. Combes, of Tisbury, made the following statement on the management of two Devonshire and Wiltshire meadows; and we quote it as he is probably the first authority on this subject in England :—

"The watering should commence the first week in November, by which time there will be a crop of young grass about two inches high. It is very desirable to have the young grass when the watering begins, that the water may percolate through the grasses so as not to flood them, otherwise they will, if flooded for any length of time, be stifled and become thin. The meadows should always be in readiness to receive the first fresh of the river from the autumnal rains, as this water is, especially after a dry summer, rich with alluvial matter. Many meadows are very much injured by being fed too late in the season, and by the treading of cattle; it should always be borne in mind that one mouthful of water-meadow grass in April is worth five or six of the same when fed in November. In general, the more the land is watered in November and December the better; but should the weather be very mild during this time, the meadows may have a few days' drying. In January the water should remain on the land about five days in six, unless the frost be so intense as to cover the meadows with ice, which is sometimes the case, when the water should be all turned off the land until a thaw takes place; the young grass will be protected by the ice and even grow under it. In February three days in four will be enough for watering. In March the irrigation should be two days in four until the water is turned out to make the land dry for feeding the grass, which will generally be fit about the last week. As soon as the sheep have fed off a portion of the meadow, or about the middle of April, the water should be again turned over that portion, but care must be taken not to allow it to remain long on the land until the grass be grown high enough to keep above the water; during the remainder of this month and the following months of May and June, two days in a week will be enough for watering. In general the grass will be fit to cut for hay by the middle of June. In July and August, or until the second hay crop be fit to cut, the water should be used sparingly, one day in six will be quite sufficient. In September and October water-meadows should be kept perfectly dry. The above rules apply to meadows that have a plentiful supply of water, but on those meadows that are short of water, which are by far the greater part, some of them requiring to be watered in five or six portions, technically called sterns, the whole of the water should remain on each stern for about five days at a time in winter, and two days at a time in summer, so that all the meadow may be watered in about twenty or thirty days in winter, and eight or ten in summer. A good flow of water, or what is called thick watering, is always to be preferred to thin watering, especially during the summer months; for a very thin watering for a week together at summer time, especially on a clay soil, is oftentimes injurious. I may here remark that night watering is preferable to watering by day, and the water will do more good in shady than in sunny weather. The water of the streams in this part of the country runs from the chalk, the upper green sand, and the upper oolite formations. That best adapted for irrigation is pure spring water.

"All water is very good for irrigation wherein certain aquatic plants grow, such as brooklime, watercresses, and water mill-foil, and when stones and other substances in the stream are thickly covered with lichen. Some of the best descriptions of grasses for water meadows are—*Anthoxanthum odoratum*, or sweet-scented vernal grass; *Festuca pratensis*, or meadow fescue grass; *Phleum pratense*, or Timothy grass; *Lolium perenne*, or rye-grass; *Agrostis stolonifera*, or fiorin grass. All these are found in the best of the Wiltshire water-meadows, especially the Timothy and fiorin grasses. I should recommend in all new water-meadows a mixture of Italian rye-grass. I will now state what may be considered the average produce of the water-meadows in South Wilts. In doing so I will take a meadow of 20 acres, depastured in spring by sheep. The spring feed of this meadow as fed in April will keep 400 couples of sheep 25 days, during which time these 400 couples will fold 10 acres of arable land, and it will after this yield in the first and second cuttings of grass about 40 tons of hay. As I have said, this may be considered the average production of these water meadows. But in order to see the capabilities of some of the best description, I will here state the annual average produce of some of them. In showing this, I will again take a 20-acre meadow, the spring grass of which, when fed by sheep from about the last week in March till the middle of May, will keep 400 couples seven weeks. During this time these couples will fold in the arable land from 15 to 20 acres. This meadow will then in two cuttings give at least 60 tons of hay. In this case there is annually put on the arable land 15 acres of spring folding and 60 tons or more of hay, thus enabling the farmer to dispense with the growing of about 20 acres of turnips and about 25 acres of field grass, or to increase the number of his sheep stock on a farm of 400 or 500 acres at least 12 per cent. I have myself, on a meadow of 13a. 3r. 26p., kept on the spring grass, in April and May, 277 couples 33 days, and 11 cows 26 days, with a little less than 10 lbs. of hay per day per cow, after which there was cut from the same meadow at least 2 tons of hay per acre, the aftermath being fed by cows and horses. I have also mown part of a water-meadow 29 times in six consecutive years, the produce of which averaged annually during the six years a little more than 40 tons of grass per acre; one year it produced more than 47 tons. In some seasons, when there is a failure of the turnip crop, the spring feed of water-meadows is exceedingly valuable; I have known it frequently let for 7*l.* or 8*l.* per acre, and in one instance I knew the spring feed of a water meadow of 6½ acres let for 80*l.*, or nearly 13*l* per acre."

On the proper seeding of land intended for a water-meadow, we quote Professor Tanner's report on the Practice of Irrigation in the 'Journal of the Bath and West of England Agricultural Society.' The following is his list :—

"*Poa aquatica* (or *Glyceria aquatica*). This water-meadow grass, also known as the reedy sweet-water grass, is a valuable plant for irrigated land, as it has a *rapid growth of good quality*.

"*Poa fluitans* (or *Glyceria fluitans*), floating sweet-water grass, is exceedingly *early* in its growth, and for this reason is generally sought after in seeding new meadows.

"*Poa trivialis*, rough-stalked meadow-grass, although not particularly early, is yet *productive*, and very desirable for water-meadows.

"*Agrostis stolonifera*, fiorin grass or marsh bent, takes a high position as a water-meadow grass. It is very productive, and yields *both early and late* herbage of good quality. It always *spreads* rapidly, and maintains a firm plant.

"*Alopecurus pratensis*, meadow foxtail grass. Its *early*, *abundant*, and *rapid growth*, together with the excellent qualities of the herbage, place this among our best grasses for meadows; and it answers very well for water-meadows, *provided* the management is good.

"*Festuca elatior*, tall meadow-fescue. This grass, although rather coarse in its nature, is *relished by stock*; it is, however, best suited to land which lies low.

"*Festuca pratensis*, meadow-fescue. The produce is *abundant* without being coarse; the *quality* is *excellent*, and its growth regular.

"*Lotus major*, great bird's-foot trefoil. Moist situations are its natural localities. It yields an *abundance of nutritious food*, and is much sought after by stock.

"*Trifolium hybridum*, hybrid clover, is not grown as much as its merits justify; it is highly esteemed on the Continent, and where it is grown in this country it answers very well. It is the *most suitable of all the clovers* for a water-meadow.

"*Phleum pratense*, meadow cat's-tail or Timothy grass. The growth of the grass is *both early* in the spring *and late* in the winter; it produces an abundance of herbage, and the *quality is exceedingly good*.

"These are the principal grasses which are suitable for irrigated land; and the following mixture of these seeds, which has been recommended,* appears to be a judicious receipt :—

	lbs.
Agrostis stolonifera	2
Alopecurus pratensis	2
Festuca elatior	2
„ pratensis	2
„ „ loliacea	2
Glyceria aquatica	1
„ fluitans	2
Lolium italicum	8
„ perenne	12
Phalaris arundinacea	2
Phleum pratense	2
Poa trivialis	3
Lotus major	2
Trifolium hybridum	1
	43

"These seeds should be sown on the land after it has been well cleaned and brought into good order by previous cultivation. The surface must be gently harrowed and then rolled, the birds kept off, and with ordinary care a good plant of grass will soon establish itself, producing herbage of the very best quality."

---

* Morton's 'Encyclopædia of Agriculture,' vol. i. p. 1001.

Lastly, we quote Professor Buckman's report on the influence of irrigation in modifying or improving the character of natural pasturage. He says:—

"Irrigation, when it can be practised, is—though acting indirectly—the most direct means of getting rid of all extraneous plants from grass herbage, and the most direct encourager of the growth of grass solely that we possess; in illustration of which we quote the subjoined table from the 'Journal of the Royal Agricultural Society,' vol. xv., part 2.

TABLE I.—SHOWING THE CHANGE OF HERBS (NOT GRASSES) UNDER IRRIGATION.

Botanical Names.	Common Names.	Proportionals.		
		Before Irrigation.	After two years' Irrigation.	After four years' Irrigation.
Ranunculus acris .	Upright Meadow Crowfoot .	1	3	1
,, bulbosus	Bulbous Crowfoot . .	3	1	..
Plantago lanceolata .	Narrow-leaved Plaintain .	3	1	1
,, media . .	Broad-leaved Plaintain . .	3	..	..
Trifolium repens .	Dutch Clover . . .	2	..	..
,, pratense .	Broad Clover . . .	1	2	2
Anthriscus vulgaris .	Common beaked Parsley .	1	2	1

"Here we see a marked decrease in bad plants and a corresponding increase in good to be distinctly traced in two years; and in four years this decrease is still more rapidly progressing; and we are enabled to state, as the result of some seven years' watching, that now the irrigated meadow presents scarcely a trace of the plants belonging to this table, but all, or nearly all, are replaced by most excellent grasses.

"The following table represents the changes which took place in twelve species of the meadow-grasses in the same time. This field trebled in value in four years, and is now worth 5*l.* an acre, its increased value being due not only to the fact of its growing grass and nothing else, but to its growing only the best kinds of grasses; for irrigation acts indirectly by killing weeds and innutritious grasses.

TABLE II.—REPRESENTING THE CHANGES OF GRASSES UNDER IRRIGATION.

Botanical Names.	Common Names.	Proportionals.		
		Before Irrigation.	After two years' Irrigation.	After four years' Irrigation.
Alopecurus pratensis .	Meadow Fox-tail Grass . .	1	2	4
Poa pratensis . .	Field Meadow Grass . .	2	3	4
,, trivialis . . .	Rough Meadow Grass . .	1	2	1
Briza media . .	Quaking Grass . . .	2	..	..
Cynosurus cristatus .	Crested Dog's-tail Grass .	2	1	..
Aira cæspitosa. . .	Hassock Grass . . .	1	..	..
Agrostis stolonifera .	Marsh Bent Grass . .	1	2	3
Dactylis glomerata .	Cock's-foot Grass . . .	1	2	3
Avena flavescens . .	Yellow Oat Grass . .	2	3	3
,, pubescens .	Soft Oat Grass . . .	1	1	1
Hordeum pratense .	Meadow Barley Grass .	1	2	2
Lolium perenne . .	Perennial Rye-grass . .	2	4	6

"These tables will at a glance show the practical bearing of irrigation as an indirect means of getting rid of extraneous meadow plants, and at the same time its direct advantage in encouraging the growth of grasses."

ISAMIC ACID. [INDIGO.]

ISAMIDE. [INDIGO.]

ISATANE. [INDIGO.]

ISATHYD. [INDIGO.]

ISATIC ACID. [INDIGO.]

ISATILIME. [INDIGO.]

ISATIMIDE. [INDIGO.]

ISATIN. [INDIGO.]

ISATINIC ACID. [INDIGO.]

ISATYDES. [INDIGO.]

ISETHIONIC ACID is one of the substances found in the residue from the preparation of ether, but may be formed directly by boiling, for some time, a strong solution of ethionic acid. The formula for ethionic acid is (C_4H_4,2HO,4SO_3);—not (C_4H_4,2HO_3,4SO_3) as represented under ETHIONIC ACID—and by ebullition is decomposed into sulphuric and isethionic acids: these may be separated from each other by neutralisation with carbonate of baryta and the isethionate of baryta obtained in tabular crystals by evaporation of the filtered solution.

Isethionic acid (C_4H_4,2HO,2SO_3) is uncrystallisable. It is isomeric with sulphovinic acid, but is well characterised by the greater stability of its salts. The general formula of the *isethionates* is (C_4H_4,HO,MO,2SO_3) or perhaps (MO,$C_4H_5S_2O_7$). They are mostly crystallisable, and when heated with hydrate of potash are decomposed into carbonate, oxalate, sulphate and sulphite of the base, hydrogen being evolved.

ISINGLASS is animal jelly, or gelatin, nearly pure. The best isinglass is prepared in Russia from the membranes of the sturgeon, especially from its air-bladder and sounds, which are remarkably large. These, when removed from the fish, are washed with cold water, and exposed a little to the air, in order that they may stiffen; the outer skin is then taken off and rejected, and the remainder cut out, and loosely twisted into rolls, according to the intended size of the pieces, which are called *staples*, and are known in commerce by the names of long and short staple, and of these the first is the best: these are dried in the air. The best sort of isinglass is used for the table and in confectionary; it is also largely employed in refining wine and beer.

Isinglass is nearly colourless, has but little taste or smell, is translucent in thin pieces, and is soluble in water. One part of it dissolved in 100 parts of hot water gives a solution which completely stiffens in cooling.

Isinglass is also dissolved by most acids readily, and also in solution of potash and soda, but not in alcohol. Several metallic salts and oxides have the property of precipitating a solution of isinglass, but corrosive sublimate does not produce this effect, which serves to distinguish it from albumen; but it resembles that substance in being precipitated by infusion of galls or of oak-bark. Isinglass is extremely nutritious.

The degree in which we are dependent on different countries for our supply of isinglass will be seen by the following figures, which refer to the importations for 1856, presenting a fair average for recent years:—From Russia, 525 cwts.; Brazil, 440; East Indies, 233; Prussia, 166; Guiana, 87; other countries, 170; equal in the whole to about 180,000 lbs.

ISIS, one of the chief deities of the Egyptians, the sister and wife of Osiris. Isis was the Goddess of the Earth; the Universal Mother; the Goddess of Fecundity, and the cow was therefore sacred to her. In the later dynasties she was the divinity of the moon, Osiris being that of the sun. By the Greeks she was identified with Demeter, and her worship became widely spread through Greece, and subsequently in Rome. She was said to have first taught men the art of cultivating corn, whence corn was always carried in processions at her festivals. The annual festival of Isis in Egypt lasted eight days, during which a general purification took place. The priests of Isis were bound to observe perpetual chastity, their heads were shaved, and they went barefooted. The goddess was often represented as a woman with the horns of a cow. She also appears with the lotus on her head and the sistrum in her hand; and her head in some instances is seen covered with a hood. Heads of Isis are a frequent ornament of Egyptian capitals on the pillars of the temples, as in the façade of the temple of Denderah, and the column from the same building, both engraved under EGYPTIAN ARCHITECTURE, where also the female figures shown in the cut of the temple of Abou-Sambul are supposed to be representations of Isis.

As the worship of Isis passed into foreign lands it assumed a foreign character and many foreign attributes, as we see from the Greek and Roman writers. Sometimes Isis is represented like Diana of Ephesus, as the universal mother, with a number of breasts. The mysterious rites of Isis were probably in their origin symbolical: on one of her statues was the inscription, "I am all that has been, that shall be; no mortal has hitherto taken off my veil." But the Isiac rites, transplanted to Italy, became a cloak for licentiousness, and they were repeatedly forbidden at Rome. Tiberius had the images of Isis thrown into the Tiber, but the worship revived, and Juvenal speaks of it in an indignant strain. The Isiac table in the Turin Museum, which is supposed to represent the mysteries of Isis, has been judged by Champollion to be the work of an uninitiated artist, little acquainted with the true worship of the goddess, and probably of the age of Hadrian.

(Plutarch's *Treatise on Isis and Osiris*, Wyttenbach's ed., ii. 441; Herod., ii. 41, 42, 123, &c.; Pausan., ii. 13, 7, and particularly x. 32, 13; Rosellini; Wilkinson, *Ancient Egyptians*, vol. iv.)

ISOCETAMIDE. [ISOCETIC ACID.]

ISOCETIC ACID ($C_{30}H_{30}O_4$). The grains of several euphorbiaceous plants yield by expression a white inodorous oil of sp. gr. ·91. By saponification with caustic soda it is separated into oleic and isocetic acids. The latter purified by crystallisation from alcohol is obtained in brilliant plates, the melting point of which is 131° Fahr.

Isocetamide ($C_{30}H_{31}NO_2$) results when the oil is heated with ammonia in a closed tube. It is a white substance fusible at 152° and not acted upon by concentrated caustic potash.

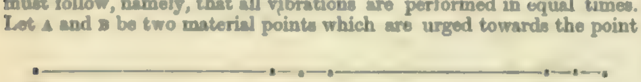
Isocetic ether is a white odourless body, solid at temperatures below 0° Fahr. [ETHEREAL SALTS.]

ISOCHROMATIC LINES are those coloured rings which appear when a pencil of polarised light is transmitted along the axis of a crystal, as mica or nitre, and is received in the eye after passing through a plate of tourmaline. If a plate of nitre, having its surfaces perpendicular to the axis of the natural prism, and highly polished, be placed between two plates of tourmaline having their axes at right angles to one another, and the system be held close to the eye, which is directed towards the sky or a sheet of white paper, there will be seen a series of oval rings, about each of two points as poles, forming together figures resembling *lemniscates*, which are curves defined by the property that the rectangle contained by two lines drawn from two points called the poles to any point in the curve is constant. The light coming directly from a lamp or candle may be used in the experiment, provided a lens of short focus be added in front, so as to condense the light on to the system, and thus furnish an illuminated field of sufficient angular extent to comprise the rings.

The curves receive their designation from the circumstance that throughout each the tint is constant. For nitre, and other biaxal crystals whose optic axes are not far apart, the tint is determined by the value of a quantity varying directly, in a given kind of crystal, as the rectangle above mentioned (the distance between the poles being supposed constant), and inversely as the thickness of the crystalline plate. In the general case, the curves are conceived to exist on the surface of a sphere of which a point in the crystal is the centre; and when the optical axes of the crystal are at a considerable distance from one another, if the curves be projected on a plane, the tint in each curve will depend on the product of the sines of the angles subtended by two lines drawn from the poles to a point in its periphery, and also upon the length of the path described by a ray of light in passing through the crystal.

ISOCHRONOUS, ISOCHRONISM (ἴσος, equal, χρόνος, time). Vibrations or oscillations which are performed in equal times are called isochronous; and isochronism is the name given to a remarkable property of all systems which are in equilibrium, namely, that when slight disturbance, be the same more or less, is given, the oscillations which take place are all performed in the same time, or so nearly in the same time, that any acceleration or retardation is totally imperceptible. Thus, when a pendulum is allowed to vibrate till it rests, it will be found that there is no perceptible difference between the vibrations of longer and shorter extent; of which any reader may satisfy himself by attaching a weight to a string, and observing the vibrations. But a still better proof may be found in a musical string: the finest ear cannot detect any difference between the pitch of a note made by a smart blow on the key of a pianoforte and that made by a gentle one; yet a very small difference in the number of oscillations per second would be perceptible, and the amount of disturbance from the position of equilibrium is twenty or thirty times greater in the first case than in the second.

When, under two different circumstances, the longer space is described in the same time as the shorter, it must be that the force acting in the first case is greater than that in the second; and it is sufficiently known from experience, that the more a system at rest is disturbed, the greater is the effort which it makes to return. But in order that there may be isochronism, it is not sufficient that the effort to return should increase with the amount of disturbance, but the increase must take place according to one particular law. This law is as follows:—the force of restitution must be always proportional to the disturbance, so that whatever force begins to act when the disturbance is a, twice as much acts when the disturbance is twice a; and so on for all proportions. That this law does prevail when the disturbance is not great, either absolutely, or so nearly that its error is extremely small, may be proved both by theory and experiment. The most complete proof is to be found in the 'Mécanique Analytique' of Lagrange. Granting the law, we can make it sufficiently apparent that the consequence must follow, namely, that all vibrations are performed in equal times. Let A and B be two material points which are urged towards the point O by pressures which are proportional to OA and OB; and further let each pressure diminish as either point approaches towards O, so as always to preserve between the pressures at any two points the proportions of the distances of those points from O. Take a minute portion of time, so small that the pressure may not vary sensibly during its continuance: then [Acceleration; Fall of Bodies] the velocities created and the spaces described in that time will be proportional to the pressures producing them. If then, during that time, A move to K and B to Q, AK and BQ (and therefore OK and OQ) will be in the proportion of OA to OB, and the points will be at K and Q, with pressures and velocities proportional to OK and OQ. In a second such instant let the points move to L and R: then KL and QR, partly due to velocities which are as OK to OQ, and partly to accelerations which are in the same proportion, will still be in the proportion of OK to OQ, or of OA to OB. Consequently the whole AL is to the whole BR in that proportion: and reasoning in this way for successive small accelerations, we show that the whole space moved over by A in any time is to that moved over by B in the same time in the proportion of OA to OB. Consequently A describes AO in the same time in which B describes BO; or the half of a vibration of A is made in the same time as half a vibration of B.



To make this process perfectly strict, recourse must be had to the considerations in Integral Calculus.

ISOCLINAL. A term applied to those lines on the surface of the globe which connect places where a magnetic needle has the same inclination or dip. The term means *equal inclination*, just as Isodynamic means *equal force*; isodynamic lines connecting those places where the total magnetic power of the earth is the same. [Magnetism, Terrestrial.]

ISOCYANURIC ACID. [Fulminuric Acid.]

ISOMERISM. There are numerous substances, especially amongst organic compounds, which contain the same elements in exactly the same proportions, but which nevertheless differ more or less widely from each other in their properties. Such substances are said to be *isomeric*, and this property or attribute is termed *isomerism*. A striking instance of this relation between a number of compounds is seen in cyanic acid and its *isomers*. Thus the following compounds, though widely different from each other in properties, all possess the same percentage composition:

Cyanic acid	C_2HNO_2
Cyamelide	C_2HNO_2
Fulminic acid	$C_4H_2N_2O_4$
Fulminuric acid	$C_6H_3N_3O_6$
Cyanuric acid	$C_6H_3N_3O_6$
Cyanilic acid	$C_6H_3N_3O_6$

When two or more isomeric compounds have the same equivalent number, as cyanic acid and cyamelide in the above list, they are said to be *metameric*. In some cases where the equivalent numbers of isomeric compounds differ, and where it may be supposed that the difference in properties results simply from the different state of condensation of their elements, as in the olefiant gas family, the bodies are said to be *polymeric*.

ISOMETRICAL PERSPECTIVE. [Perspective.]

ISOMORPHISM. This term, employed in chemistry and crystallography, strictly signifies similarity of form, but chemists restrict the term to such bodies as are not only similar in crystalline form but also in chemical composition; thus diamond, magnetic oxide of iron, and alum, all possess the same crystalline form, that of the octohedron—but they are not regarded as isomorphous, because they possess no analogy in chemical composition. On the other hand spinelle-ruby (MgO,Al_2O_3), magnetic oxide of iron (FeO,Fe_2O_3), and chrome iron ore (FeO,Cr_2O_3) are termed isomorphous because they not only crystallise in the same form, but are analogous in their composition. The following are some of the most important isomorphous groups:—

I.

Alumina	Al_2O_3
Sesquioxide of iron	Fe_2O_3
Oxide of chromium	Cr_2O_3
Ilmenite	$FeTiO_3$

II.

Sulphuric acid	SO_3
Selenic acid	SeO_3
Chromic acid	CrO_3
Manganic acid	MnO_3

III.

Chloride of potassium	KCl
Bromide of potassium	KBr
Iodide of potassium	KI
Fluoride of potassium	KF

For further details regarding isomorphism, and also for a description of the doctrine of *dimorphism*, see Miller's 'Chemical Physics.'

ISOPERIMETRICAL. [Variation, Calculus of.]

ISO'SCELES (ἴσος, equal, σκέλος, leg, the *c* usually pronounced hard, like *k*), a term applied to a triangle of which two sides (or legs) are equal.

ISOTARTARIC ACID. [Tartaric Acid.]

ISOTEREBENTHIN. [Turpentine.]

ISOTHERMAL LINES. [Meterorology; Temperature, Terrestrial, Distribution of.]

ISSUE. (Law.) [Pleading.]

ISSUE is an ulcer artificially formed for the purpose of maintaining a constant purulent discharge from some part of the body. It is usually made by placing one or more beads or peas on an incision through the integuments in one of the limbs, or in the neighbourhood of a diseased part, and there retaining them by adhesive plaster, so as to prevent the wound from healing, and keep it in a constant state of suppuration. Other issues are made by rubbing caustic potash, or potash and quicklime, on a part of the skin till it is destroyed and sloughs, and by keeping open the ulcer thus formed, either with peas, or very stimulant dressings. Setons are another form of issue, made by passing a broad flat needle beneath a portion of the skin, and retaining in the passage thus formed either a skein of silk or a flat band of caoutchouc. The moxa and the actual cautery are also sometimes employed with the same view.

The use of issues for the cure of constitutional diseases, under the idea that they remove noxious principles from the blood, is now entirely abandoned; but they are sometimes had recourse to in order to restore an habitual discharge which has been checked by the cure of any chronic local particularly skin disease, and the cessation of which has seemed to give rise to congestion of the head or of any internal organ. But the principal value of issues is as counter-irritants, by establishing a disease which is of itself unimportant in the neighbourhood of one which by its situation is more serious; and hence they are amongst the most important means in the cure of chronic inflammations of many internal organs, and especially of those of the joints and of the spine.

ISSUE PEAS are round bodies employed for the purpose of maintaining irritation in a wound of the skin which is called an issue. [ISSUE.] It is a matter of indifference of what substance the peas are composed, so long as they do not introduce poisonous matters into the wound. The seed of the common garden pea is frequently used; but this is apt to putrify or sprout. It is however more common to use the young unripe fruits of the common orange (*Citrus aurantium*). The fruits are dried and afterwards turned in a lathe before they are used as issue peas. The unripe oranges, dried, are sold under the name of orangettes or Curaçoa oranges. The rootstock of the *Iris florentina* is also formed into peas, and used for keeping up the discharge from issues.

ISTHMIAN GAMES. The Isthmia were one of the four great national festivals of Greece, the others being the Olympia, Pythia, and Nemea. The Isthmia were celebrated under the presidency of the Corinthians, near Corinth, on the isthmus connecting Peloponnesus with the continent, at intervals of four years, corresponding with the recurrence of the other festivals above-mentioned, so that each year had its solemnity. The Isthmian games were first established in honour of Melicertes, the son of Ino (Paus., i. 44), but were reorganised by Theseus in honour of Poseidon, the presiding deity of the isthmus. The crowns bestowed on victors were of pine-leaves, or, later, wreaths of ivy. After the fall of Corinth the Isthmia were celebrated under the direction of the Sicyonians, until Corinth was re-built, when they were restored to the Corinthians, and continued to be celebrated till the establishment of Christianity. As all these games were similar in their object, contests, and ceremonies, it will be sufficient to refer for further details to the article on the principal of them, the Olympia. [OLYMPIAN GAMES.]

ITACONAMIC ACID ($C_{10}H_7NO_6$). A brown amorphous acid, formed by heating the itaconate of ammonia. Its salts are very instable. In like manner, by heating the itaconate of aniline *itaconanilic acid* ($C_{10}H_6(C_{12}H_5)NO_6$) or *phenyl-itaconamic acid* is obtained.

ITACONANILIDE ($C_{10}H_8(C_{12}H_5)_2N_2O_4$), *Phenyl-itaconamide.* An unimportant derivative from citric acid. [ANILIDES.]

ITACONANILIC ACID. [ITACONAMIC ACID.]

ITACONIC ACID ($C_{10}H_4O_6,2HO$). When citric or aconitic acid is distilled, two liquids are obtained in the receiver, the lighter of which mixes perfectly with water, whilst the heavier, which is oleaginous, combines with it slowly, and becomes a crystalline mass, to this a sufficient quantity of boiling water is to be added to dissolve the oleaginous liquid and the crystals formed, and the solution is to remain exposed to the air; after some days' spontaneous evaporation, crystals of itaconic acid are deposited, which are transparent and hard; these are to be purified by repeated crystallisations from water.

The properties of the itaconic acid thus prepared are :—It crystallises in rhombic tables or rhombic octohedrons. It has no smell, but possesses a very strong acid taste. It dissolves in 17 parts of water at 50°, and in 10 parts at 68°, and boiling water dissolves much more. It is soluble in alcohol and in ether; at 248° the crystals lose no weight. At 320° they melt, exhaling white irritating vapours, and volatilise without leaving any residue when the heat is continued. When subjected to distillation they decompose into anhydrous citraconic acid and water.

ITALIAN ARCHITECTURE. Instead of comprising buildings of every style and class to be met with in Italy, the term "Italian Architecture" is generally restricted to signify that generic style formed by the revival of the Roman orders, and the adaptation of them, and other features derived from works of the same age, to buildings of every kind, domestic as well as public. Without such limitation, the term would apply to buildings having nothing else in common than their locality, to the Ca d'Oro at Venice, no less than to the works of Palladio, and such modernised *Palladianism* as is exhibited in the design of the Teatro Fenice in the same city. Even with such limitation, the style presents so many varieties, both in regard to modes of treatment and taste of design, as to render it difficult to draw up a succinct account of it, if more be attempted than to explain the character of the orders and other leading external features, with their application, and the taste generally manifested in architectural design.

Italian architecture, thus restricted, arose in that remarkable era in Italian history when the Medici had gathered about them the learning, the poetry, and the art of the day, and the revived study of classic literature having imbued the educated classes with a deep reverence for everything classic, works of art, as well as literature, were anxiously moulded according to a Roman type. Instead, however, of proposing to themselves the remains of Roman antiquity as models to be freely followed in the same spirit, and modified as circumstances should require, Italian architects, in endeavouring to fix a new style founded upon the ancient orders, began by reducing the orders themselves to the strictest mechanical system possible; notwithstanding that for the Doric and Ionic they had no better guide than the few debased and insipid specimens which occur in Roman works, and the ambiguous explanations given in the text of Vitruvius, whom they looked up to as an infallible oracle.

Italian architecture then is, allowance being made for local varieties, a style founded upon the Roman antique as interpreted by the writings of Vitruvius, and reduced to a methodical system by Alberti, Vignola, and Palladio. It was, however, founded rather on the Coliseum, the baths, triumphal arches and other secular buildings of the Romans than on their temples. Its greatest triumphs were in the palaces and civic buildings, rather than in the churches, which it secularised, and as the phrase is, paganised. But the Italian architects in their revival of ancient art made no effort to *reproduce* the ancient buildings. Whilst they followed with pedantic strictness the teaching of Vitruvius and Alberti in reference to the orders separately considered, they allowed themselves the utmost licence in their application of them. Theirs was a new combination of parts, not a repetition of the whole; their principle was that of the adaptation of antique Roman forms and details to modern Italian buildings. These forms and details were often applied with little consideration or discrimination, but the general effect is nevertheless rich and imposing; and to Brunelleschi, Sansovino, and Palladio must be accorded the honour of having created a new and noble style of palatial and domestic architecture, rich in resources, and admitting of the combination of broad simplicity and dignity of treatment with freshness, elegance, and picturesqueness in the details. But it is essentially a civic style of architecture; the architecture of narrow streets and public places; an architecture whose buildings were to be seen close at hand and admired in detail, not like the ancient temples or mediæval cathedrals to awe the mind by grandeur of mass, as well as by the severe simplicity or multitudinous variety of subordinate parts.

The characteristic features of the Italian architecture of the 15th and 16th centuries, may be stated briefly, but cannot be so stated without leaving the statement exceedingly imperfect. As has been said, the characteristic which distinguished this from the architecture of the preceding centuries was the strict use of the Roman orders. But then these orders were employed rather as a decorative than a constructive feature; and applied without regard to classic precedent: and precedent being departed from in the primary instance, its neglect throughout followed as a necessary consequence. Thus different orders, or repetitions of the same order, being applied to the several stories of buildings whose fronts were pierced with windows, it became unavoidable to abandon all proportion of intercolumniation, and to space the columns according to the breadth of the piers and the apertures between them; which in turn left hardly any other alternative than to engage the columns themselves, that is, to attach either half or three-quarter columns to the walls, because insulated columns placed so wide apart from each other would have had an exceedingly poor and meagre effect. And where one order was placed above another, two straggling rows of low insulated pillars—for low they must be in comparison with the entire height of the building,—instead of at all ornamenting a building, would have incumbered it with what would have resembled stages of scaffolding.

For a somewhat similar reason, either pilasters were substituted for engaged columns, or the entablature was made to break over every column; for if, instead of being thus broken, the entablature were continued from column to column in each story, overhanging the face of the wall, it would produce an appearance of heaviness as well as weakness. One result of this practice of giving a separate order to each story is, that the columns become comparatively insignificant, both in proportion to the entire front and to the windows between them; more especially when the columns are further shortened by being placed on pedestals. In fact windows and doors are generally the predominant features in Italian composition, even where two series are comprised within one order, being generally more prominent in their cornices and pediments than the other projections. They are often decorated with smaller columns or pilasters, and Palladio has sometimes loaded them with recumbent figures on the raking cornices of their pediments. Sometimes, as in the upper order of the Procuratie Nuove, by Scamozzi, at Venice, the windows (decorated with a lesser order) are carried up to the height of the capitals. In instances like these the ornamental details may be in imitation of the members of an ancient order, but the antique character is gone. Even where the windows are kept more subordinate to the order itself, the effect of the order is frequently diminished by the addition of a heavy attic pierced with windows occupying its entire length, and surmounted in turn by a balustrade, having perhaps a formal row of statues on its pedestals, which viewed at a little distance assume the appearance of so many pinnacles on the summit of the building, whilst the balusters themselves in such cases suggest the idea of perforated battlements.

Another distinctive feature of Italian architecture is the frequent use of circular, and the introduction of broken, pediments over doors and windows. Cornices are sometimes made important features in the composition, but often they are rendered subordinate or altogether dispensed with, the balustrade being as we have seen made the crowning feature. In some of the richer examples sculpture is freely and very effectively introduced, though occasionally in a somewhat heterodox manner. Sculptured friezes and elegantly carved vases also contribute largely to the general effect.

But whilst much of the Italian architecture is *microstylar*, that is, has a separate small order to each floor, or horizontal division of a façade above the ground floor, much of it is *astylar*, that is, without columns; the windows and arches being the chief features of the composition, and either a full entablature or a bold, rich, and carefully proportioned cornicione crowning the entire mass. This large and simple mode of treatment was greatly affected by the Florentine and Roman architects of the period of the revival.

The example and influence of the revived Italian architecture was soon felt throughout Europe [RENAISSANCE ARCHITECTURE], and the Italian architects were everywhere looked up to and followed as the great masters of the profession, until the archæological researches of the last century, and particularly the examination of the architectural remains of ancient Greece, led to the desire for a closer imitation of classic, and especially of Greek forms: a fashion which has in its turn given way before the Gothic re-action.

In our own country the Italian style was first introduced, with any pretence to closeness of imitation, by Inigo Jones, and the Banqueting House, Whitehall, may be referred to as a favourable example both of the genius of the architect, and of the imitative Italian of the beginning of the 17th century. One of the latest English examples, prior to the eruption of the Greek furor, is Chambers's Somerset House; the court of the Strand portion of which is a good example of a late modified Italian style, where an order is placed on a decorated basement. In our own day the Italian style has been re-introduced with great though not unquestioned success. Sir Charles Barry, the first we believe to adopt it, has applied it with great ability in several of his more important domestic buildings. The Travellers' and the Reform club-houses in Pall Mall, both by him, will, with the adjoining Carlton Club (by Mr. Sidney Smirke), afford the reader a good idea of Italian architecture. All the three are copies, or adaptations, of celebrated Italian buildings: The astylar Travellers is an imitation of the Palazzo Pandolfini, at Florence; the Reform, a free adaptation of the Palazzo Farnese, at Rome; the microstylar Carlton, a direct copy from Sansovino's famous Library of St. Mark, Venice. Several of the other London club-houses are Italian in style, and more or less direct copies of existing Italian buildings.

ITCH, or as it is termed by nosologists, Scabies or Psora, is a disease of the skin, of which the most prominent symptom is a constant and intolerable itching. The eruption consists most commonly of minute vesicles filled with a clear watery fluid, and slightly elevated on small pimples; but its character is often obscured by a mixture of papulæ and pustules with the vesicles. Hence the disease has been divided into distinct species according to the predominance of each kind of eruption; but the distinction is artificial, and of no practical utility. The eruption occurs principally on the hands and wrists, and in those parts most exposed to friction, as the spaces between the fingers and the flexures of the joints. After a time it extends from these parts to the arms, legs, and trunk; but very rarely, if ever, appears on the face.

The itch is attended by no constitutional disorder, except in those severest forms in which the eruption consists chiefly of large pustules, surrounded by considerable inflammation of the adjacent skin. It never appears to arise spontaneously; but, where cleanliness is not strictly observed, it is easily communicated by contact. It is entirely due to the presence of a minute acarus under the skin known by the name of *Sarcoptes scabiei*. With the destruction of the insect the disease disappears. [ACARIDÆ, in NAT. HIST. DIV.]

A certain specific for the cure of the itch, which never gets well without treatment, is the local application of sulphur; all the parts on which the eruption is visible should be plentifully smeared with the *unguentum sulphuris* every night, or every night and morning, till the cure is perfected, which will require from three days to a fortnight, according to the severity and extent of the disease. The ointment must remain on the parts after each application, and occasional warm baths ought to be used during the treatment.

IVORY, the substance which composes the teeth or tusks of elephants, is extensively used in the arts for making or embellishing numberless small articles in almost universal use. The principal supplies of elephants' teeth to this country are derived from the west coast of Africa and from Ceylon. The remaining imports are chiefly from the coast of Barbary, the Cape of Good Hope, Madagascar, and Siam. The United States of America also send to this country some of the ivory which they import; and fossil ivory occasionally reaches England from Russia. The demand has much increased within the last few years, and the supply can scarcely keep up with it. A great quantity is now brought over by the Peninsular Company's steamers from Alexandria, sometimes as much as 20,000*l*. worth in one cargo. This portion of the trade consists chiefly of wild elephants' tusks which have been shed in the deserts of Arabia, and bought up by the Pacha of Egypt for sale to English buyers. The teeth and tusks of the elephant, hippopotamus, wild boar, and narwhal, all form ivory of various kinds; though the the tusk of the elephant is that which usually goes by the name. The fossil mammoth, often found in Siberia, was a kind of elephant; and the ivory of the tusks is very similar to that of the elephant of the present day. The Russians almost wholly make use of this kind of ivory. Some of the mammoth tusks are 10 feet long, solid to within 6 inches of the end, and weigh 168 lbs. Pianoforte makers occasionally veneer the white keys of those instruments with mammoth ivory.

For purposes of manufacture ivory is cut up by means of saws set in steel frames; the saws are from 15 to 30 inches long, from 1½ to 3 inches wide, and 1-50th of an inch thick; with the teeth sharp but coarse. From the peculiar curves and twists of each tusk, great art is required to cut up the ivory with least waste. Veneers are cut in a ratio of 30 to an inch thickness of ivory; and as the sawdust, together with the scraping from after processes, effect a waste of one-half, it often happens that 60 finished ivory veneers will be no more than an inch in aggregate thickness. The thin plates are used chiefly for miniatures and for memorandum-books. The Russians, some years ago, devised a mode of cutting wood veneers out of solid blocks, by slicing it spirally from the surface towards the centre, like unfolding a roll of cloth; and M. Pape, a pianoforte manufacturer at Paris, afterwards applied this method to the cutting of ivory veneers. He can produce sheets measuring 150 inches by 30; and with such sheets he has veneered the entire surface of pianofortes. Ivory forms a fine and delicate material for graduated scales in mathematical instruments; but it is liable to expand and contract, under alternations of weather, to an inconvenient degree—insomuch that the Tithe Commissioners have refused to permit the use of ivory scales in laying down the areas and boundaries of land.

Ivory, after being cut with the saw, is smoothed and polished by various means—such as very fine glass paper, or emery paper; whiting and water applied by wash leather; oil on a bit of rag; putty powder; Flanders brick, Trent sand, or powdered chalk, wetted, and applied with flannel or a brush; or scraping and then rubbing on soft wheels. The list wheels employed by ivory-workers consist of 10 to 20 circular pieces of woollen cloth, screwed tightly between two wooden discs of rather smaller diameter; the cloth forms a pliant edge projecting beyond the wood; such wheels when moistened with Trent sand, are used for polishing parasol handles and similar articles. The chief demand in England for ivory is for making knife-handles and combs.

Ivory is often engraved by the French artists. They first cover the surface with a ground of wax or composition; then etch the design in this ground; then bite it in by a dilute solution of nitrate of silver; then wash in distilled water, dry with blotting-paper, and expose for one hour to the sun's rays. When the ground has been removed by the action of essence of turpentine, the design presents itself as a series of brownish lines, which soon become nearly black. The design may be developed in other tints if, instead of nitrate of silver, there be used nitro-muriate of gold or platinum, or nitrate of copper. Sometimes the ivory itself is engraved, and the lines filled in with hard black varnish. Another mode of ornamenting ivory is to engrave a design on a copper plate, take an impression on paper, transfer this impression to the ivory, stop out the blank portions with guiacum varnish, submit the ivory to the action of dilute acid, and then melt or wash off the varnish; there will result a tinted engraving on the surface of the ivory.

Mr. Cheverton in 1850 patented a mode of making what he terms artificial ivory. It consists in giving an ivory-like surface to gypsum or alabaster. The ornaments or other articles made of this material are exposed for forty-eight hours to a temperature of 300° Fahr., by which the moisture is driven off. They are then immersed till saturated in olive oil or in white hard varnish; and after being steeped several times in warm water, they are polished with whiting or putty powder, by which they obtain an ivory-like surface. M. Franchi has devised a somewhat similar mode of imitating ivory by preparing a mixture of 32 parts plaster of Paris with 1 of Italian yellow ochre; the materials are reduced to powder, sifted, mixed, liquefied with water, cast in moulds, dried in the open air, baked in an oven, and soaked while hot for a quarter of an hour in a hot mixture of equal parts of spermaceti, white wax, and stearine; the cast is finally brushed while warm, and polished with a tuft of cotton wool when cold.

The curious substance called *vegetable ivory*, is the seed of a genus of plants named *Phytelephas*, from *phuton* and *elephas*, the Greek version of its English name. An account of it, and of its uses, will be found under PHYTELEPHAS, in NAT. HIST. DIV.

IVORY BLACK. [BONE BLACK.]

IXOLITE. A mineral hydrocarbon resembling *hartite*.

J

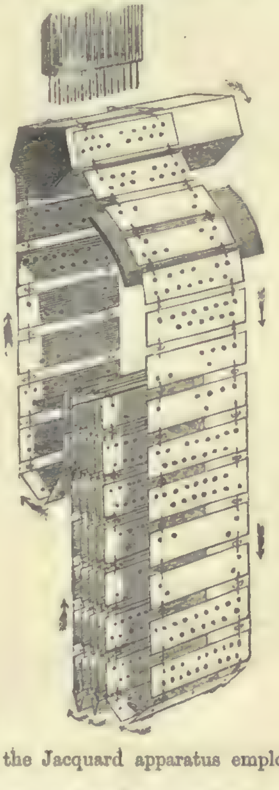
J, in the English language, has a sibilant sound, closely connected with that of the syllable *di* before a vowel. [ALPHABET.] It has a similar sound in the French tongue; but in German it is pronounced altogether as our *y* before a vowel. What its pronunciation was in Latin may admit of dispute, for although it is generally laid down that its power with the Romans was the same as with the Germans, there is reason for thinking that our own sound of the letter was not unknown to the ancient inhabitants of Italy. The name of Jupiter was undoubtedly written originally Diupiter, so Janus was at first Dianus, just as the goddess Diana was called by the rustics Jana. (See D and I.) The argument might be strengthened by comparing the Latin *jungo* with the Greek ζευγνυμι, Jupiter with Ζευ πατερ, &c., and also by referring to the modern Italian forms, *Giogo*, *giovare*, *giovenco*, *giovane*, &c. There is no absurdity in supposing that two pronunciations may have co-existed in the same country. As to the form of the letter *j*, it was originally identical with that of *i*, and the distinction between them is of recent date. Exactly in the same way, among the numerals used in medical prescriptions, it is the practice to write the last symbol for unity with a longer stroke, *vj vij*, *viij*.

In the Spanish language *j* represents a guttural, and is now used instead of *x*, which had the same power: thus Jeres rather than Xeres is the name of the town which gives its title to the wine called by us sherry. For the changes to which *j* is liable, see D, G, and I.

JACOBINS, is the name of a faction which exercised a great influence on the events of the first French Revolution. This faction originated in a political club formed at Versailles, about the time of the meeting of the first National Assembly, and which was composed chiefly of deputies from Brittany, who were most determined against the court and the old monarchy, and some also from the South of France, among whom was Mirabeau. When the National Assembly removed its sittings to Paris (October 19, 1789), the Breton club followed it, and soon after established its meetings in the lately suppressed convent of the Jacobins, or Dominican monks, in the Rue St. Honoré. From this circumstance the club and the powerful party which grew from it acquired the name of Jacobins. During the year 1790 the club increased its numbers by admitting many men known for violent pinciples, which tended not to the establishment of a constitutional throne, but to the subversion of the monarchy. A schism broke out between these and the original Jacobins, upon which Danton, Marat, and other revolutionists seceded from the club, and formed themselves into a separate club called "Les Cordeliers," from their meetings being held in a suppressed convent of Franciscan friars. [DANTON, in BIOG. DIV.] The Cordeliers openly advocated massacre, proscription, and confiscation, as a means of establishing the sovereignty of the people. In 1791 the Cordeliers reunited themselves with the Jacobin club, from which they expelled the less fanatical members, such as Louis Stanislas Freron, Legendre, and others. From that time, and especially in the following year 1792, the Jacobin club assumed the ascendancy over the legislature; the measures previously discussed and carried in the club being forced upon the assembly by the votes of the numerous Jacobin members, and by the out-door influence of the pikemen of the suburbs, with whom the club was in close connection. The attack on the Tuileries, in August, 1792, the massacres of the following September, the suppression of royalty, and most of the measures of the reign of terror, originated with the club of the Jacobins. [ROBESPIERRE, in BIOG. DIV.] The club had affiliations all over France. After the fall of Robespierre in July, 1794, the convention passed a resolution forbidding all popular assemblies from interfering with the deliberations of the legislature. The Jacobins, however, having attempted an insurrection in November, 1794, in order to save one of their members, Carrier, who had been condemned to death, for his atrocities at Nantes, the convention ordered the club to be shut up; and Legendre, one of its former members, with an armed force dissolved the meeting, and closed the hall. The spirit of the club, however, survived in its numerous adherents, and continued to struggle against the legislature and the Executive Directory, until Bonaparte put an end to all factions, and restored order in France. The name of Jacobin has since continued to be used, though often improperly applied, like other party names, to denote men of extreme democratical principles, who wish for the subversion of monarchy and of all social distinctions, and are not over-scrupulous about the means of effecting their object.

JACQUARD APPARATUS. The Jacquard loom—or, more correctly, Jacquard appendage to the loom—is the most beautiful of all contrivances connected with weaving. For a notice of the life of the inventor, see JACQUARD, in BIOG. DIV.

The apparatus which cost Jacquard so much thought and anxiety is an appendage to the loom, intended to elevate or depress the warp-threads for the reception of the shuttle. There is a hollow prismatic box, whose surfaces are pierced with a great number of holes; and to each face of the box is fitted a card also perforated: or rather, there are for each particular pattern to be woven a large number of cards, all of equal size, and equal in size to each face of the box. The perforations in the cards, where they occur, are correspondent in position with some of the holes in the box; but in almost every card the holes are fewer in number than those on each face of the box. All the cards are linked together by hinges or joints, in such a manner that, as the box rotates on a horizontal axis, the cards in succession lie flat on its several faces. The cards for one pattern may be several hundreds in number, and all form an endless chain. The box may have four, five, or more faces, according to circumstances. The principle of action may be explained thus:—Supposing each face to have 100 perforations, then there are 100 small bars or needles ranged in a group in exactly the same order as the holes in the faces of the box, the ends of the bars being immediately opposite the holes. Each bar or needle is a lever by which certain warp-threads are governed, in such a way that, when the bars are moved longitudinally, the warp-threads become elevated or depressed. Now if the box have a reciprocating motion, so that one of its faces shall strike against the ends of the bars, the ends of all the bars will pass into the holes in the box, if the face be not covered with a card; but if it be so covered, some of the bars will pass through the holes of the card into the holes in the box, while others, at the unperforated parts of the card, will be driven aside. Thus the bars become unequally acted on, and they in their turn act unequally on the warp-threads, depressing some, raising others, and leaving the remainder stationary; and the cards are so perforated as to lead to the production of a pattern from this inequality of action. The mode in which the cards lie on the box may be seen in the annexed cut, which represents a form of the Jacquard apparatus employed in the bobbin-net machine.



The Jacquard apparatus was first intended for and applied to silk-weaving, but it has been found applicable to the bobbin-net and various other fancy manufactures. Its characteristic value has been thus stated by Mr. Porter: "The elaborate specimens of brocade which used to be brought forward as evidence of skilfulness on the part of the Spitalfields weavers of former days, were produced by only the most skilful among the craft, who bestowed upon their performances the most painful amount of labour. The most beautiful products of the loom in the present day are, however, accomplished by men possessing only the ordinary rate of skill; while the labour attendant upon the actual weaving is but little more than that demanded for making the plainest goods."

has a separate small order to each floor, or horizontal division of a façade above the ground floor, much of it is *astylar*, that is, without columns; the windows and arches being the chief features of the composition, and either a full entablature or a bold, rich, and carefully proportioned cornicione crowning the entire mass. This large and simple mode of treatment was greatly affected by the Florentine and Roman architects of the period of the revival.

The example and influence of the revived Italian architecture was soon felt throughout Europe [RENAISSANCE ARCHITECTURE], and the Italian architects were everywhere looked up to and followed as the great masters of the profession, until the archæological researches of the last century, and particularly the examination of the architectural remains of ancient Greece, led to the desire for a closer imitation of classic, and especially of Greek forms: a fashion which has in its turn given way before the Gothic re-action.

In our own country the Italian style was first introduced, with any pretence to closeness of imitation, by Inigo Jones, and the Banqueting House, Whitehall, may be referred to as a favourable example both of the genius of the architect, and of the imitative Italian of the beginning of the 17th century. One of the latest English examples, prior to the eruption of the Greek furor, is Chambers's Somerset House; the court of the Strand portion of which is a good example of a late modified Italian style, where an order is placed on a decorated basement. In our own day the Italian style has been re-introduced with great though not unquestioned success. Sir Charles Barry, the first we believe to adopt it, has applied it with great ability in several of his more important domestic buildings. The Travellers' and the Reform club-houses in Pall Mall, both by him, will, with the adjoining Carlton Club (by Mr. Sidney Smirke), afford the reader a good idea of Italian architecture. All the three are copies, or adaptations, of celebrated Italian buildings: The astylar Travellers is an imitation of the Palazzo Pandolfini, at Florence; the Reform, a free adaptation of the Palazzo Farnese, at Rome; the microstylar Carlton, a direct copy from Sansovino's famous Library of St. Mark, Venice. Several of the other London club-houses are Italian in style, and more or less direct copies of existing Italian buildings.

ITCH, or as it is termed by nosologists, Scabies or Psora, is a disease of the skin, of which the most prominent symptom is a constant and intolerable itching. The eruption consists most commonly of minute vesicles filled with a clear watery fluid, and slightly elevated on small pimples; but its character is often obscured by a mixture of papulæ and pustules with the vesicles. Hence the disease has been divided into distinct species according to the predominance of each kind of eruption; but the distinction is artificial, and of no practical utility. The eruption occurs principally on the hands and wrists, and in those parts most exposed to friction, as the spaces between the fingers and the flexures of the joints. After a time it extends from these parts to the arms, legs, and trunk; but very rarely, if ever, appears on the face.

The itch is attended by no constitutional disorder, except in those severest forms in which the eruption consists chiefly of large pustules, surrounded by considerable inflammation of the adjacent skin. It never appears to arise spontaneously: but, where cleanliness is not strictly observed, it is easily communicated by contact. It is entirely due to the presence of a minute acarus under the skin known by the name of *Sarcoptes scabiei*. With the destruction of the insect the disease disappears. [ACARIDÆ, in NAT. HIST. DIV.]

A certain specific for the cure of the itch, which never gets well without treatment, is the local application of sulphur; all the parts on which the eruption is visible should be plentifully smeared with the *unguentum sulphuris* every night, or every night and morning, till the cure is perfected, which will require from three days to a fortnight, according to the severity and extent of the disease. The ointment must remain on the parts after each application, and occasional warm baths ought to be used during the treatment.

IVORY, the substance which composes the teeth or tusks of elephants, is extensively used in the arts for making or embellishing numberless small articles in almost universal use. The principal supplies of elephants' teeth to this country are derived from the west coast of Africa and from Ceylon. The remaining imports are chiefly from the coast of Barbary, the Cape of Good Hope, Madagascar, and Siam. The United States of America also send to this country some of the ivory which they import; and fossil ivory occasionally reaches England from Russia. The demand has much increased within the last few years, and the supply can scarcely keep up with it. A great quantity is now brought over by the Peninsular Company's steamers from Alexandria, sometimes as much as 20,000*l*. worth in one cargo. This portion of the trade consists chiefly of wild elephants' tusks which have been shed in the deserts of Arabia, and bought up by the Pacha of Egypt for sale to English buyers. The teeth and tusks of the elephant, hippopotamus, wild boar, and narwhal, all form ivory of various kinds; though the the tusk of the elephant is that which usually goes by the name. The fossil mammoth, often found in Siberia, was a kind of elephant; and the ivory of the tusks is very similar to that of the elephant of the present day. The Russians almost wholly make use of this kind of ivory. Some of the mammoth tusks are 10 feet long, solid to within 6 inches of the end, and weigh 168 lbs. Pianoforte makers occasionally veneer the white keys of those instruments with mammoth ivory.

For purposes of manufacture ivory is cut up by means of saws set in steel frames; the saws are from 15 to 30 inches long, from 1½ to 3 inches wide, and 1-50th of an inch thick; with the teeth sharp but coarse. From the peculiar curves and twists of each tusk, great art is required to cut up the ivory with least waste. Veneers are cut in a ratio of 30 to an inch thickness of ivory; and as the sawdust, together with the scraping from after processes, effect a waste of one-half, it often happens that 60 finished ivory veneers will be no more than an inch in aggregate thickness. The thin plates are used chiefly for miniatures and for memorandum-books. The Russians, some years ago, devised a mode of cutting wood veneers out of solid blocks, by slicing it spirally from the surface towards the centre, like unfolding a roll of cloth; and M. Pape, a pianoforte manufacturer at Paris, afterwards applied this method to the cutting of ivory veneers. He can produce sheets measuring 150 inches by 30; and with such sheets he has veneered the entire surface of pianofortes. Ivory forms a fine and delicate material for graduated scales in mathematical instruments; but it is liable to expand and contract, under alternations of weather, to an inconvenient degree—insomuch that the Tithe Commissioners have refused to permit the use of ivory scales in laying down the areas and boundaries of land.

Ivory, after being cut with the saw, is smoothed and polished by various means such as very fine glass paper, or emery paper; whiting and water applied by wash leather; oil on a bit of rag; putty powder; Flanders brick, Trent sand, or powdered chalk, wetted, and applied with flannel or a brush; or scraping and then rubbing on soft wheels. The list wheels employed by ivory-workers consist of 10 to 20 circular pieces of woollen cloth, screwed tightly between two wooden discs of rather smaller diameter; the cloth forms a pliant edge projecting beyond the wood; such wheels when moistened with Trent sand, are used for polishing parasol handles and similar articles. The chief demand in England for ivory is for making knife-handles and combs.

Ivory is often engraved by the French artists. They first cover the surface with a ground of wax or composition; then etch the design in this ground; then bite it in by a dilute solution of nitrate of silver; then wash in distilled water, dry with blotting-paper, and expose for one hour to the sun's rays. When the ground has been removed by the action of essence of turpentine, the design presents itself as a series of brownish lines, which soon become nearly black. The design may be developed in other tints if, instead of nitrate of silver, there be used nitro-muriate of gold or platinum, or nitrate of copper. Sometimes the ivory itself is engraved, and the lines filled in with hard black varnish. Another mode of ornamenting ivory is to engrave a design on a copper plate, take an impression on paper, transfer this impression to the ivory, stop out the blank portions with guiacum varnish, submit the ivory to the action of dilute acid, and then melt or wash off the varnish; there will result a tinted engraving on the surface of the ivory.

Mr. Cheverton in 1850 patented a mode of making what he terms artificial ivory. It consists in giving an ivory-like surface to gypsum or alabaster. The ornaments or other articles made of this material are exposed for forty-eight hours to a temperature of 300° Fahr., by which the moisture is driven off. They are then immersed till saturated in olive oil or in white hard varnish; and after being steeped several times in warm water, they are polished with whiting or putty powder, by which they obtain an ivory like surface. M. Franchi has devised a somewhat similar mode of imitating ivory by preparing a mixture of 32 parts plaster of Paris with 1 of Italian yellow ochre; the materials are reduced to powder, sifted, mixed, liquefied with water, cast in moulds, dried in the open air, baked in an oven, and soaked while hot for a quarter of an hour in a hot mixture of equal parts of spermaceti, white wax, and stearine; the cast is finally brushed while warm, and polished with a tuft of cotton wool when cold.

The curious substance called *vegetable ivory*, is the seed of a genus of plants named *Phytelephas*, from *phuton* and *elephas*, the Greek version of its English name. An account of it, and of its uses, will be found under PHYTELEPHAS, in NAT. HIST. DIV.

IVORY BLACK. [BONE BLACK.]

IXOLITE. A mineral hydrocarbon resembling *hartite*.

J

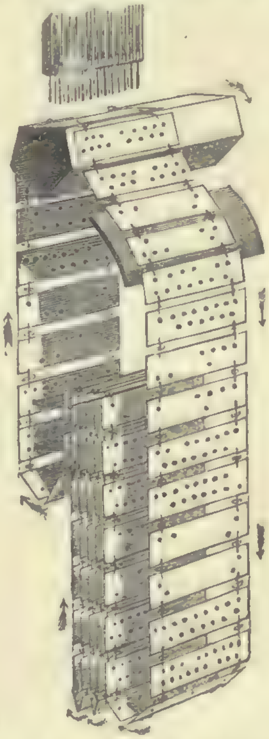
J, in the English language, has a sibilant sound, closely connected with that of the syllable *di* before a vowel. [ALPHABET.] It has a similar sound in the French tongue; but in German it is pronounced altogether as our *y* before a vowel. What its pronunciation was in Latin may admit of dispute, for although it is generally laid down that its power with the Romans was the same as with the Germans, there is reason for thinking that our own sound of the letter was not unknown to the ancient inhabitants of Italy. The name of Jupiter was undoubtedly written originally Diupiter, so Janus was at first Dianus, just as the goddess Diana was called by the rustics Jana. (See D and I.) The argument might be strengthened by comparing the Latin *jungo* with the Greek ζευγνυμι, Jupiter with Ζευ πατερ, &c., and also by referring to the modern Italian forms, *Giogo, giovare, giovenco, giovane*, &c. There is no absurdity in supposing that two pronunciations may have co-existed in the same country. As to the form of the letter *j*, it was originally identical with that of *i*, and the distinction between them is of recent date. Exactly in the same way, among the numerals used in medical prescriptions, it is the practice to write the last symbol for unity with a longer stroke, *vj vij, viij*.

In the Spanish language *j* represents a guttural, and is now used instead of *x*, which had the same power: thus Jeres rather than Xeres is the name of the town which gives its title to the wine called by us sherry. For the changes to which *j* is liable, see D, G, and I.

JACOBINS, is the name of a faction which exercised a great influence on the events of the first French Revolution. This faction originated in a political club formed at Versailles, about the time of the meeting of the first National Assembly, and which was composed chiefly of deputies from Brittany, who were most determined against the court and the old monarchy, and some also from the South of France, among whom was Mirabeau. When the National Assembly removed its sittings to Paris (October 19, 1789), the Breton club followed it, and soon after established its meetings in the lately suppressed convent of the Jacobins, or Dominican monks, in the Rue St. Honoré. From this circumstance the club and the powerful party which grew from it acquired the name of Jacobins. During the year 1790 the club increased its numbers by admitting many men known for violent pinciples, which tended not to the establishment of a constitutional throne, but to the subversion of the monarchy. A schism broke out between these and the original Jacobins, upon which Danton, Marat, and other revolutionists seceded from the club, and formed themselves into a separate club called "Les Cordeliers," from their meetings being held in a suppressed convent of Franciscan friars. [DANTON, in BIOG. DIV.] The Cordeliers openly advocated massacre, proscription, and confiscation, as a means of establishing the sovereignty of the people. In 1791 the Cordeliers reunited themselves with the Jacobin club, from which they expelled the less fanatical members, such as Louis Stanislas Freron, Legendre, and others. From that time, and especially in the following year 1792, the Jacobin club assumed the ascendancy over the legislature; the measures previously discussed and carried in the club being forced upon the assembly by the votes of the numerous Jacobin members, and by the out-door influence of the pikemen of the suburbs, with whom the club was in close connection. The attack on the Tuileries, in August, 1792, the massacres of the following September, the suppression of royalty, and most of the measures of the reign of terror, originated with the club of the Jacobins. [ROBESPIERRE, in BIOG. DIV.] The club had affiliations all over France. After the fall of Robespierre in July, 1794, the convention passed a resolution forbidding all popular assemblies from interfering with the deliberations of the legislature. The Jacobins, however, having attempted an insurrection in November, 1794, in order to save one of their members, Carrier, who had been condemned to death, for his atrocities at Nantes, the convention ordered the club to be shut up; and Legendre, one of its former members, with an armed force dissolved the meeting, and closed the hall. The spirit of the club, however, survived in its numerous adherents, and continued to struggle against the legislature and the Executive Directory, until Bonaparte put an end to all factions, and restored order in France. The name of Jacobin has since continued to be used, though often improperly applied, like other party names, to denote men of extreme democratical principles, who wish for the subversion of monarchy and of all social distinctions, and are not over-scrupulous about the means of effecting their object.

JACQUARD APPARATUS. The Jacquard loom—or, more correctly, Jacquard appendage to the loom—is the most beautifnl of all contrivances connected with weaving. For a notice of the life of the inventor, see JACQUARD, in BIOG. DIV.

The apparatus which cost Jacquard so much thought and anxiety is an appendage to the loom, intended to elevate or depress the warp-threads for the reception of the shuttle. There is a hollow prismatic box, whose surfaces are pierced with a great number of holes; and to each face of the box is fitted a card also perforated: or rather, there are for each particular pattern to be woven a large number of cards, all of equal size, and equal in size to each face of the box. The perforations in the cards, where they occur, are correspondent in position with some of the holes in the box; but in almost every card the holes are fewer in number than those on each face of the box. All the cards are linked together by hinges or joints, in such a manner that, as the box rotates on a horizontal axis, the cards in succession lie flat on its several faces. The cards for one pattern may be several hundreds in number, and all form an endless chain. The box may have four, five, or more faces, according to circumstances. The principle of action may be explained thus:—Supposing each face to have 100 perforations, then there are 100 small bars or needles ranged in a group in exactly the same order as the holes in the faces of the box, the ends of the bars being immediately opposite the holes. Each bar or needle is a lever by which certain warp-threads are governed, in such a way that, when the bars are moved longitudinally, the warp-threads become elevated or depressed. Now if the box have a reciprocating motion, so that one of its faces shall strike against the ends of the bars, the ends of all the bars will pass into the holes in the box, if the face be not covered with a card; but if it be so covered, some of the bars will pass through the holes of the card into the holes in the box, while others, at the unperforated parts of the card, will be driven aside. Thus the bars become unequally acted on, and they in their turn act unequally on the warp-threads, depressing some, raising others, and leaving the remainder stationary; and the cards are so perforated as to lead to the production of a pattern from this inequality of action. The mode in which the cards lie on the box may be seen in the annexed cut, which represents a form of the Jacquard apparatus employed in the bobbin-net machine.



The Jacquard apparatus was first intended for and applied to silk-weaving, but it has been found applicable to the bobbin-net and various other fancy manufactures. Its characteristic value has been thus stated by Mr. Porter: "The elaborate specimens of brocade which used to be brought forward as evidence of skilfulness on the part of the Spitalfields weavers of former days, were produced by only the most skilful among the craft, who bestowed upon their performances the most painful amount of labour. The most beautiful products of the loom in the present day are, however, accomplished by men possessing only the ordinary rate of skill; while the labour attendant upon the actual weaving is but little more than that demanded for making the plainest goods."

Since Mr. Porter wrote, the extensions in the use of the Jacquard apparatus have been numerous and important; and many changes in the mode of working have been gradually introduced. Messrs Lamb of Kidderminster, in applying it to carpet weaving, have devised modes of ensuring a greater certainty of action, and a diminished liability to disarrangement. Mr. Mackenzie, a Spitalfields manufacturer, has substituted a number of compound needles for the revolving bars. Mr. Martin has devised a combination of perforated pattern papers, vertical needles, and presser bars, for selecting and acting upon a series of horizontal rods, by means of which the warp threads of the pattern are determined on. The old method involved a great wear and tear of cardboard, which induced some of the carpet manufacturers to substitute sheet iron. It has however since been found practicable to use a continuous strip of paper instead of a series of cards linked together. The stripe can be rapidly cut from a previously perforated sheet of paper; and any number of duplicates may be produced. It required a long time to prepare the cards for a new pattern, and this lessened the willingness to introduce novel designs, on account of the expense; but by lessening the cost and weight, through the introduction of paper great scope is given for the display of artistic variety. Messrs. Crossley, the eminent carpet manufacturers of Halifax, employ the Jacquard apparatus very largely in weaving the richer designs of carpet; it is also much used by the manufacturers of waistcoat fabrics at Huddersfield.

Some progress has been made towards the application of electricity, as a moving power, to the Jacquard apparatus. If the attempts prove successful, they will be noticed in WEAVING.

JAGANATH. [JUGGERNAUTH.]

JAINAS, a religious sect of the Hindus. The name is derived from the Sanskrit *jina*, "victorious," which is the generic name of the deified saints of this sect.

The Jainas are very numerous in the southern and western provinces of Hindustan; they are principally engaged in commerce, and from their wealth and influence form a very important division of the population of the country. The history and opinions of this sect are also interesting from their striking similarity to the chief peculiarities of the religion of Buddha. The earliest information concerning this sect was given in the 9th vol. of the 'Asiatic Researches,' in an 'Account of the Jains, collected from a priest of this sect, at Mudgeri, translated for Major Mackenzie;' in 'Particulars of the Jains,' by Dr. Buchanan: and in 'Observations of the sect of Jains,' by Colebrooke. Several particulars concerning them are also given in Buchanan's 'Journey from Madras through Mysore,' &c.; Wilks's 'Historical Sketch of the South of India;' in the work of the Abbé du Bois; and in Ward's 'View of the History, Literature, and Religion of the Hindus.' Information still more important is given in the 1st volume of the 'Transactions of the Royal Asiatic Society,' by Colebrooke, 'On the Philosophy of the Hindus;' by Major Delamain, 'On the Srâwaks, or Jains;' by Colebrooke, Dr. Hamilton, and Col. Franklin, 'On Inscriptions in Jain Temples in Behar;' by Dr. Hamilton, 'On the Srâwaks, or Jains;' and also in the 2nd volume of the Transactions, by Major Todd, 'On the Religious Establishments in Mewar.' But the most complete account of this sect is given by Prof. Wilson, in his 'Sketch of the Religious Sects of the Hindus.' ('As. Res.,' vol xvii.)

A view of the literature of the Jainas is given by Wilson in his 'Descriptive Catalogue of the MSS., &c., of Col. Mackenzie,' vol. ii., pp. 144–162. The Jainas have their own Purânas and other religious works, which are principally devoted to the history of the Tôrthankaras, or deified teachers of the sect. The chief Purânas are supposed to have been written by Jina Sena Achârya, who was probably the spiritual preceptor of Amoghaversha, king of Kânchi, at the end of the 9th century of the Christian era. They have also their own works on astronomy, astrology, medicine, the mathematical sciences, and the form and disposition of the universe, of which a list is given in Wilson's 'Descriptive Catalogue.' "But the list there given is very far from including the whole of Jain literature, or even a considerable proportion. The books there alluded to are in fact confined to Southern India, and are written in Sanskrit or the dialects of the peninsula; but every province of Hindustan can produce Jain compositions, either in Sanskrit or its vernacular idiom; whilst many of the books, and especially those that may be regarded as their Scriptural authorities, are written in the Prakrit or Magadhi, a dialect which, with the Jains as well as the Buddhas, is considered to be the appropriate vehicle of their sacred literature." (Wilson, 'As. Res.,' vol. xvii., pp. 242-3.) The Jainas are also said to have a number of works entitled Siddhantas and Agamas, which are to them what the Vedas are to the Brahmanical Hindus.

The Jainas are considered by the Brahmans to form no part of the Hindu Church. The principal points of difference between them and the Brahmanical Hindus are—1st, a denial of the divine origin of the Vedas; 2ndly, the worship of certain holy mortals who have acquired by self-mortification and penance a power which renders them superior to the gods; and 3rdly, extreme tenderness for animal life. These doctrines and customs are essentially the same as those of the Buddhists. The Jainas do not entirely reject the gods of the Hindu mythology; but they consider them greatly inferior to the Jinas, who are the object of their religious adoration. The statues of all or part of these are in all their temples, sculptured in black or white marble. They are distinguished from each other in colour and stature: two are represented as red, two as white, two as blue, two as black, and the rest as of a golden hue or yellowish-brown. Of these Jinas the most celebrated are Pârsvanâtha and Mahâvira, who alone can be regarded as having any historical existence.

The origin of this sect has been a subject of much dispute. Some have endeavoured to prove that Buddhism and Jinism are more ancient than the Brahmanical religion; but several arguments have already been brought forward in another part of this work which render this hypothesis exceedingly improbable. [BUDDHISM.] It has, on the contrary, been maintained with greater probability, from the absence of all allusion to Jinism in the ancient Brahmanical and Buddhistic works, and from the comparatively late date of all inscriptions and monuments relating to the Jainas which have yet been discovered, none being earlier than the 9th century, that the sect of the Jainas did not become of any importance till the 8th or 9th century of the Christian era. The striking similarity between the Buddhists and Jainas renders it probable that they had the same origin, and that Jinism is merely another form of Buddhism, accommodated to the prejudices of the Brahmanical Hindus. In the southern provinces of Hindustan, where the Jainas are the most numerous, the distinction of castes is preserved among this sect; but it appears probable, from many circumstances, that originally they had no distinction of caste; and even in the present day, in the upper provinces, the Jainas all profess to be of one caste, namely, the Vaisyas, which is equivalent to their being of no caste at all. The Jainas also allow Brahmans to officiate as the priests of their temples. The period in which we have supposed Jinism to have first risen into importance coresponds with the time in which the Buddhists were finally expelled from Hindustan. (Wilson's 'Sanskrit Dictionary,' 1st edit., preface, pp. xv.-xx.) It therefore appears probable that those Buddhists who were allowed to remain adopted the opinions and practices of Jinism, which may previously have existed as an insignificant division of the Buddhistic faith. In the 11th and 12th centuries the religion of the Jainas appears to have been more widely diffused than at any other period. Many princes in the southern part of the peninsula embraced this faith; but it gradually lost much of its power and influence, in consequence of the rapid progress of the Vaishnavas and Saivas.

The Jainas were anciently called Arhatas, and are divided into two sects, of which the former is called Vivasanas, Muktavasanas, Mucktâmbaras, or Digambaras, in reference to the nakedness of this order; and the latter Swetâmbaras, "clad in white," because the teachers of this sect wear white garments. The former are the more ancient. In the early philosophical writings of the Hindus, in which the Jainas are mentioned, they are almost always called Digambaras, or Nagnas, "naked." The term Jaina rarely occurs, and that of Swetâmbara still more rarely. These two sects, though differing from each other in very few points, oppose one another with the bitterest animosity.

The Jainas are also divided into Yatis and Srâvakas, clerical and lay, the former of whom subsist upon the alms of the latter. The religious ritual of the Jainas is very simple. The Yatis dispense with acts of devotion at their pleasure; and the Srâvakas are only bound to visit a temple daily, where some of the images of the Jinas are erected, and make a trifling offering of fruit and flowers, accompanied by a short prayer. The Jaina temples are generally superior in size and beauty to those which belong to the Brahmanical religion. [INDIA, ARCHITECTURE OF.] Bishop Heber has given an account of his visit to one of these temples, from which strangers are usually excluded with jealous precautions. "The priest led us," he says, "into a succession of six small rooms, with an altar at the end of each, not unlike those in Roman Catholic chapels, with a little niche on one side, resembling what in such churches they call the *piscina*. In the centre of each room was a large tray with rice and ghee strongly perfumed, apparently as an offering, and men seated on their heels on the floor, with their hands folded as in prayer or religious contemplation. Over each of the altars was an altar-piece, a large bas-relief in marble, containing, the first five, the last in succession twenty-five figures, all of men sitting cross-legged, one considerably larger than the rest, and represented as a negro. He, the priest said, was their god; the rest were the different bodies he had assumed at different epochs, when he had become incarnate to instruct mankind. The doctrines he had delivered on these occasions make up their theology; and the progress which any one has made in these mysteries entitles him to worship in one or more of the successive apartments which were shown us." ('Journal,' i., p. 292.)

The moral code of the Jainas is expressed in five *Mahâvratas*, or "great duties:" 1st, refraining from injury to life; 2nd, truth; 3rd, honesty; 4th, chastity; 5th, freedom from worldly desires. There are also four *Dhermas*, or "merits:" liberality, gentleness, piety, and penance.

JALAP is obtained from several plants of the tribe of the *Convolvulaceæ*. The best is procured from the *Exogonium purga* (Bentham), called also *Ipomæa purga*. It is a native of Mexico, growing high up in the mountains. Jalap is chiefly shipped from Vera Cruz, and takes its name from the town of Xalapa, or Jalapa, in the interior. It is best when collected in March or April, before the young shoots have begun to be developed. The large root, which often weighs 50 pounds, is divided into portions, which are hung in nets over a fire, and dried in ten or twelve days. It occurs in commerce in irregular round or pear-shaped masses, which, when good, are dry, hard, with a brown shining fracture, resinous, not light, somewhat tough. It is often adulterated with portions of the root of white bryony, which, however, are white, or when old, gray, not heavy, very brittle, fracture not resinous, spongy, without smell, but with very bitter taste. Dried pears are also often substituted for it; but they may be detected by being laid open, when the core will be seen, containing the seeds. Analysed by Cadet de Gassicourt, 100 parts of the dry root yielded resin 10, gummy extractive 44, woody fibre 29, starch, albumen, salts of lime, and potass, &c. According to the more recent analysis of Guibourt, some specimens yield 17 per cent. of resin: false rose-scented jalap as little as 3 per cent. Jalapina, or rhodeoretia, is an alkaloid discovered by Mr. Hume. It is a transparent, colourless, odourless, tasteless resin. These qualities recommend it to children, for whose complaints it is extremely well suited.

Ipomœa turbethum yields the jalap of the East Indies. But there is scarcely a single species of this genus that does not yield more or less of a purgative principle, and generally called jalap. These, and nearly all substitutes for the genuine jalap, are enumerated by Dr. Theodor Martius, in his 'Pharmakognosie des Pflanzenreiches,' Erlangen, 1832. The so-called *twigs* (stipites) of jalap, are really the roots or tubers of *Ipomœa orizabensis* (Ledanois), *Convolvulus orizabensis* of Pelletan. *Ipomœa leatatoides*, Benth., 'Bot. Register,' January, 1841. It yields the inferior, light, or male jalap, and contains an alkaloid called Pararhodeoretia.

Its excellence depends upon the quantity of resin; a white jalap (from *C. Mechoacanna*) is sometimes met with, which contains only 2 per cent of resin; its dose must be five or six times as great as that of the genuine jalap.

Jalap is ranged with the drastic purgatives, and where one of a resinous kind is desired, is that usually selected. Its action is generally certain, and when in combination with other substances, mild and speedy. It does not seem greatly to influence the nerves of the abdomen, but rather the vascular system of the pelvis and lymphatic system of the intestines. It is given in obstruction of the liver, vena-porta, and diseases connected with these organs, such as hypochondriasis, melancholia, jaundice, dropsy, and intermittent fevers; but at the commencement of common fevers, along with calomel, it is of great utility; also in the inflammatory or turgescent stage of hydrocephalus, and in the treatment of worm cases.

JALAPIC ACID ($C_{66}H_{59}O_{35}$?). An uncrystallisable acid produced by the metamorphosis of jalapin under the influence of alkalies. It is homologous with convolvulic acid.

JALAPIN. [CONVOLVULIN.]

JALAPINOL ($C_{32}H_{31}O_7$?). A crystalline substance insoluble in cold water, produced by the action of boiling dilute acids upon jalapin and jalapic acid. Treated with caustic alkalies it forms *jalapinolic acid* ($C_{32}H_{30}O_8$?)

JALAPINOLIC ACID. [JALAPINOL.]

JALLOFFS, or YALLOFFS, a negro tribe who occupy a considerable tract of country between the rivers Senegal and Gambia. They are considered as the finest race of negroes in this part of Africa; they are tall and well made, their features are regular, and their physiognomy open. Though bordering on the Foolahs and Mandingos, they differ from both, not only in language, but in features. The noses of the Jalloffs are not so much depressed nor the lips so protuberant as among the generality of Africans, but their skin is of the deepest black. They are chiefly employed in agriculture, and have made some progress in the useful arts, especially in the manufacture of cotton cloth, which they make better than any of the neighbouring tribes. They are divided into several independent states, or kingdoms, which are frequently at war either with their neighbours or with each other.

JAMAICINE is found with *Surinamine* in the *Geoffrœa inermis* and *G. Surinamensis*. They are crystallisable alkaloids, capable of forming salts with the acids, which are precipitated by tannin and corrosive sublimate.

JANIZARIES is the name of a Turkish militia once formidable but now extinct. The origin of this body dates from the reign of Amurath, or Murad I., who, after having overrun Albania, Bosnia, Servia, and Bulgaria, claimed the fifth part of the captives, from among whom he chose the young and able-bodied, and had them educated in the Mohammedan religion, and for the military profession. These recruits, being duly disciplined, were formed into a distinct body of infantry, divided into ortas, or battalions, and they were consecrated and blessed by a celebrated dervish called Hadji Bektash, who gave them the name of Yeni Cheri, or "New Soldiers." They soon became the terror of the enemies of the Ottomans: being completely weaned from their friends and homes, they were enthusiastically devoted to their sultan as their common father; and a strict discipline, regular pay, and constant service gave them habits of order and obedience far superior to the irregular bodies which formed at the time the armies of the princes of Christendom. After the death of Solyman the Magnificent, and the general though gradual decay of the Ottoman warlike spirit, when the sultans no longer took the field in person, the Janizary body was no longer recruited exclusively from choice and young captives, but by enrolments of Osmanlees, who being born and bred in the faith of Islam, had not the zeal of proselytes, and were besides connected by ties of consanguinity and friendship with the body of the people around them, and not exclusively devoted to the will of the sultan. In 1680 Mohammed IV. abolished the law by which the Christian rayahs, or subjects of the Porte, were obliged to give a portion of their children to the sultan to be educated in the Mohammedan faith and enrolled into the militia. By the original laws of their body the Janizaries could not marry, but by degrees the prohibition was evaded, and at last totally disregarded. Their children's names were then inscribed on the rolls of their respective ortas; and their relations and friends, men often unfit for any warlike service, obtained a similar honour, which gave them certain privileges and protection from the capricious oppression of their rulers. In this manner a crowd of menials, low artisans, and vagabonds, came to be included in the body of Janizaries; even rayahs and Jews purchased for money the same privilege; but all this motley crew lived out of the barracks, where only a few in time of peace were present at the appointed hours for receiving their soups or rations. Military exercises were abandoned; the Janizaries merely furnished a few guards and patroles for the city, many of them being only armed with sticks; and they never assembled as a body except on pay-day, when they defiled two by two before their nazirs, or inspectors. Still they were formidable to the government from their numbers, which were scattered all over the empire, and their influence and connections with the mob of the capital. They repeatedly mutinied against the sultans, and obliged them to change their ministers, or even deposed them. In our own days they dethroned Selim; and in the beginning of the reign of the late Sultan Mahmood they broke out into a dreadful insurrection which lasted three days, and in which the Vizir Mustapha Bairactar lost his life. In both instances they were impelled by their hatred of the Nizam Djedid, or new troops, disciplined after the European fashion. At last Mahmood resolved to put down the Janizaries; and having for several years matured his plan with the advice of his favourite Halet Effendi, and gained over their aga and others of their principal officers, he issued an order that every orta or division should furnish 150 men to be drilled according to the European tactics. This, as he had foreseen, led to a revolt; the Janizaries assembled in the square of the Etmaidan, reversed their soup-kettles according to their custom in such cases, and, invoking the name of their tutelary saint Hadji Bektash, they began by attacking and plundering the houses of their enemies. But the body of topjis, or cannoniers, the bostandjis, or guards of the seraglio, and the galiondjis, or marines, were prepared; the sultan, mufti, and the ulemas, assembled in the mosque of Achmet, pronounced a curse and a sentence of eternal dissolution on the body of the Janizaries; the sandjak shereef, or sacred standard, was unfurled, and a general attack on the Janizaries began, who, cooped up in the narrow streets, were mowed down by grape-shot, and the rest were despatched by the muskets and the yataghans of their enemies, or burned in their barracks. About 25,000 Janizaries are said to have been engaged in the actual revolt, and most of them perished: the others concealed themselves or were exiled into Asia. This carnage took place in June, 1825, and from that time the Janizaries as a body have ceased to exist. Macfarlane, in his 'Constantinople in 1828,' gives a vivid account of that catastrophe.

JANSENISTS, a sect which appeared in the Roman Catholic church about the middle of the 17th century. They professed not to attack the dogmas but only the discipline of that church, which however stigmatised them as heretical in some of their tenets. They took their name from Janssen, or Jansenius, bishop of Ypres in the Netherlands, who published a book entitled 'Augustinus,' in which he supported, by means of passages from the writings of St. Augustine, certain principles concerning the nature and efficacy of divine grace which appear to partake greatly of Calvin's doctrine of predestination. This question of grace and predestination had already been discussed in the church at various times, and had proved a stumbling-block to many theologians. Michael Baius, professor at Louvain, had been condemned in 1567 by a papal bull, and obliged to disown seventy-six propositions taken from his writings, chiefly concerning that abstruse subject. Jansenius however died quietly at Ypres in 1638, and it was not till several years after his death that some Jesuit theologians, on examining his book, discovered in it the following five propositions, which they denounced as heretical:—1. That there are certain commandments of God which even righteous men, however desirous, find it impossible to obey, because they have not yet received a sufficient measure of grace to render obedience possible. 2. That nobody can resist the influence of inward grace. 3. In our fallen state of nature it is not required, in order that we be accounted responsible beings, that we should be free from the internal necessity of acting, provided we are free from external constraint. 4. The Semi-Pelagians were heretical in maintaining that the human will has the choice of resisting or obeying the internal grace. 5. That to maintain that Christ died for all men, and not solely for those who are predestinated, is Semi-Pelagianism.

After much controversy, these five propositions were condemned by a bull of Pope Innocent X., in the year 1653, as impious and blasphemous, and the bull was received by the French prelates, and promulgated throughout France with the king's consent. Several learned men, who disliked the Jesuits and their latitudinarian system of ethics, wrote not to defend the five propositions, but to prove that these propositions did not exist in the book of Jansenius, at least not in the sense for which they were condemned. The Jesuits again appealed to the pope, and a curious question arose for the pope, which was, to determine the exact meaning of an author who was dead. Alexander VII. however, by a new bull, in 1656, again condemned Jansenius's book as containing the five propositions in the sense ascribed to them by the former bull. Arnauld and other learned men of Port-Royal persisted in denying this assumed meaning; and thus they, and all those who thought like them, received the appellation of Jansenists. A formulary was now drawn out conformable to the papal bull, which all ecclesiastical persons in France were required to sign, on pain of being suspended from their functions and offices. A great many refused, and this occasioned a schism in the French church, which lasted many years. Arnauld, Pascal, Nicole, and other reputed Jansenists attacked vehemently the corruption, discipline, and morality of the church, and the Jesuits as supporters of that relaxation. [PASCAL, in BIOG. DIV.] They also inculcated the necessity of mental rather than outward or ceremonial devotion; they promoted the knowledge of the Scriptures among the people, and they encouraged general education by numerous good works which came from the press of Port-Royal. Meantime the controversy with Rome continued, although Clement IX., in 1668, entered into a sort of compromise with the French non-subscribing clergy, and Innocent XI. behaved with still greater moderation towards them. But Father Quesnel's 'Moral Observations on the New Testament,' published in 1698, added fuel to the flame. Quesnel, being now considered at the head of the Jansenist party, was driven into exile; Louis XIV., urged by his Jesuit confessor, suppressed the monastery of Port-Royal in 1709; and Pope Clement XI., in 1713, fulminated the bull 'Unigenitus' against 101 propositions of Father Quesnel's work. [CLEMENT XI. in BIOG. DIV.] A fresh contention now arose; a great part of the French clergy, many of whom were not Jansenists, including Cardinal de Noailles, appealed from the bull of the pope to a general council. The Regent d'Orléans however insisted on unconditional submission to the bull, and the recusants, or "appellants," were persecuted and driven into exile. This persecution made many fanatics, and Jansenism became a name for a set of visionaries and impostors. A certain Abbé Paris, who had been one of the appellants, and had died in 1727, was said to perform miracles from his tomb. For an investigation of these pretended miracles, see Bishop Douglas's 'Criterion, or Miracles Examined.' Next came a set of men called Convulsionnaires, who were seized with spasms and ecstasies; and others who were styled Flagellants, who whipped themselves in honour of the Saint Abbé Paris. This frenzy lasted for years, and the government by harsh measures only increased it; in fact it became mixed up with political discontent, and the parliament of Paris took the part of the appellants. At last the paroxysm subsided, having had the effect of discrediting the name of Jansenism, which, as a sect, never afterwards revived, though its opinions are still held by many. As the original Jansenists maintained the absolute independence of the civil power on ecclesiastical authority, and as even in ecclesiastical matters they were not favourable to the supremacy of the Roman see, their principles had the effect of inducing many of the French clergy to take the oath to the constitution of 1791; these were called "prêtres insermentés," and were considered as schismatics by the see of Rome. The Jansenist principles extended to Italy, especially to Tuscany, where bishop Ricci and his partisans also effected a temporary schism.

JANUARY, the first month in our present Calendar, was also the first month in the Roman Calendar. It was not the first month of the year in this country till 1752, when the legislature, by an act passed in the preceding year, altered the mode of reckoning time from the Julian to the Gregorian style. At this time it was directed that the legal year, which then commenced in some parts of this country in March, and in others in January, should universally be deemed to begin on the first of January. January derives its name from Janus. Macrobius expressly says it was dedicated to him because from its situation, it might be considered to be retrospective to the past, and prospective to the opening year. It consists of thirty-one days, though originally of only thirty days. The Anglo-Saxons called January *Wolf-monath*.

JANUS, one of the most ancient and highest of the Roman deities. In mythological history, Janus is the earliest of the Italian kings, and reigned in Latium, being contemporary with Saturn. He was succeeded by Picus and Faunus, who as well as himself, were worshipped by the Etruscans and Romans. Janus, by some accounts, was the son of the sun, and his attributes appear to connect him with sun-worship. He is the porter of heaven: he opens the year, the first month being named after him; he presides over the seasons, whence he is sometimes represented with four heads (Janus Quadrifrons), and his temples in that capacity were built with four equal sides, but only one entrance. He presides over production. He is the keeper of earth, sea, and sky; the guardian deity of gates, on which account he is commonly represented with two faces, because every door looks two ways; and thus he, the heavenly porter, can watch the east and west at once without turning. (Ovid, 'Fast.,' i. 140.) He usually carries a key in his left hand and a staff in the other. (Ib., 99.) His temples at Rome were numerous. In war time the gates of the principal one, that of Janus Quirinus, were always open; in peace they were closed to retain the wars within (Ib., 124); but they were shut once only between the reign of Numa and that of Augustus. In reference to this attribute he has the epithets of Clusius and Patuleius, the shutter and opener. All his attributes, numerous and complicated as they are, appear to have reference to this notion of opening and shutting, and are explained, by those who see in Janus a modification of the sun, in reference to the phenomena of day and night, and the pervading vivifying influence of the solar rays; though, as has been implied, the ancients also connected his name with *janua*, a door. As to the probable origin of the word Janus, see the articles ARTEMIS, and the letter J.

JAPANNING, is the art of producing a highly varnished surface on wood, metal, or other hard substance, sometimes of one colour only, but more commonly figured and ornamented. The process has received its name from that of the islands of Japan, whence articles so varnished were first brought to Europe; though the manufacture is also extensively practised by the Chinese, Siamese, Birmese, and other nations of the extreme east of Asia, among whom it was suggested most probably by the possession of a tree, which affords with little preparation a beautiful varnish, exceedingly well adapted for the purpose, and which hardens better than those prepared in Europe.

The appearance of japanned work is as various as the taste and fancy of the artists employed in it. Sometimes it is a plain black or red, with a gilded or painted border; or it is an imitation of marble, of fine grained or rare wood, or of tortoiseshell; sometimes a drawing, in which high finish, brilliant colour, and showy patterns are more sought than good design; and occasionally fine copperplate engravings are applied to a japanned surface. In all cases the work is highly polished and varnished. Japanning is applied to ladies' work-boxes and work-tables, toilet-boxes, cabinets, tea-caddies, fire-screens, tea-trays, bread-baskets, snuffers and trays, candlesticks, and a variety of other articles. A good deal of common wood-painting is also called japanning; but this differs from the more ordinary painter's work in little else than in using turpentine instead of oil to mix the colours with. Bedsteads, dressing-tables, wash-hand-stands, bed-room chairs, and similar articles of furniture are painted in this way.

Three processes are usually required in japanning; laying the ground, painting, and finishing. In addition to these processes, whenever the matter to be japanned is not sufficiently smooth to receive the varnish, or when it is too soft or coarse, it is sometimes prepared or primed before any of the proper japanning processes are applied. The preparatory mixture or priming is composed of size and chalk; it is put on with a brush like paint, and when perfectly dry it is brought to an even surface by rubbing with rush, and is then smoothed by a wet rag. The best japanners, however, disapprove of the use of priming, because its brittleness is very detrimental to the firmness of the varnishes laid over it; they use no substances which are of themselves unfit for receiving a varnish, or which they are unable to bring to a sufficiently smooth surface. For wood hard and fine enough to receive a varnish without priming, and for metals, paper, and leather, the only preparation necessary is a coat or two of varnish. In all these processes it is a rule to allow a day or two to intervene after every operation, that the work may be thoroughly dry.

When the work has been prepared, the ground is laid on; this is either all of one colour, or marbled, or done in imitation of tortoiseshell. The grounds are the ordinary pigments mixed with varnish, laid on smoothly with a brush: when thoroughly dry they are varnished, and afterwards polished by rubbing with a rag and tripoli or rotten stone; and, if the ground be white, with putty or starch and oil. The varnish used is either copal, seed lac, or made of the gums animi and mastic. The mode of laying the grounds varies greatly. That which is now generally followed is to lay on one or two thick coats of colour mixed with varnish, then to varnish three or four times, and afterwards to dry the work thoroughly in a stove. The colours are flake-white or white-lead, Prussian-blue, vermilion, Indian-red, king's-yellow, verdigris, and lamp-black; intermediate tints are made by mixtures of these; and an imitation of tortoiseshell is produced by vermilion and a varnish of linseed-oil and umber. When a particularly gorgeous appearance is desired, the ground may be laid entirely in gold. This is produced by going over the work with japanner's gold size, which, when dry enough to bear touching with the finger, but still soft and clammy, is covered with gold-dust, applied on a piece of soft wash-leather. Any other metallic dust may be laid on in the same way. Many receipts are given for preparing the japanner's gold size, but nearly all agree in making linseed-oil and gum animi the basis of the composition. A curious and very striking mode of laying the ground, called the *dip*, was formerly much practised. It was done by dropping small quantities of coloured varnish in a trough of water, over the surface of which it immediately spread in curious and often beautiful ramifications; into these the article was dipped; the colour was thus transferred to the work, and when dried was varnished and polished in the usual manner.

The work when thoroughly dry will now be ready for painting. Showiness and brilliancy are chiefly sought for in japanning, and bright colours with gold and bronze dust are largely employed. The colours are tempered with oil or varnish, and the metallic powders laid on with gold size. Copper-plate engravings or wood-cuts may also be executed in japan work. In this process the engraving is first printed off upon fine paper which has been previously prepared by a thick coat of isinglass or gum water. When the print is perfectly dry, it is applied with its face downwards upon the japan ground covered with a thin coat of copal varnish; the paper is then moistened on the back with a sponge dipped in warm water, which in a few minutes dissolves the isinglass or gum, and the paper which is thus loosened is gently taken away, leaving the impression on the work. Indian ink or other drawings upon paper may be transferred to the japanned ground in the same way. A more expeditious and very effectual mode of transferring an engraving is to print upon a smooth thick layer of a composition of glue, treacle, and whiting, which will receive an impression as perfectly as a sheet of paper: the composition, which is elastic and very flexible, may be immediately laid down upon the japanned surface, which will thus receive nearly as good an impression as if it could have been itself applied to the engraving.

In whatever manner the work has been painted or printed, or if all addition to the plain colour of the ground has been dispensed with, nothing now remains but the finishing. This is a very simple process. The workman chooses one of the before-named varnishes, and passes it over the work with a brush several times, until he judges the coating thick enough to bear the polish. It is an important precaution not to begin the varnishing until the preceding work is thoroughly dry, and to dry perfectly each coat before laying on a succeeding one. A hot stove is used in the best establishments to aid in drying the work. When thick enough, the varnish is polished by rubbing it with a rag dipped in finely-powdered tripoli or rotten-stone; towards the end of the operation a little oil is also applied to the rag, and the work is completed by rubbing with oil alone, to clear off the powder or any other impurity.

A peculiar species of japan-work is described under BURMESE WARE.

Japanning, as understood in the Birmingham and Wolverhampton district, is chiefly applied to the coating of sheet iron-trays, saucepans, and other articles, with black varnish or japan. It is carried on to an immense extent, and is largely executed by women and children. A more delicate variety of the art, also centered in Birmingham, will be found noticed under PAPIER MACHÉ.

JAPONIC ACID. [TANNIC ACIDS.]

JASHER, BOOK OF (סֵפֶר הַיָּשָׁר), or 'the book of the upright,' is twice referred to in the Old Testament as a work of authority. (Josh. x. 13; 2 Sam. i. 18.) Many conjectures have been formed concerning the author and contents of this book; but we have no means of arriving at any satisfactory determination on the subject, since the work appears to have been lost before the time of the Babylonish captivity. Some critics have imagined it to be the same work as the book of Judges, which is evidently incorrect from the quotation in the book of Samuel; St. Jerome and some Jewish authors that it was the book of Genesis; others, as Bishop Lowth and Gesenius, have maintained that it was a collection of national songs.

In the year 1751, a printer of the name of Ilive published a pretended translation of the book of Jasher, which was said to have been translated from the original Hebrew by Alcuin of Britain. This work was republished at Bristol in 1829. An interesting account, and an elaborate exposure of this literary forgery is given in Horne's 'Introduction to the Scriptures.' There are also two Rabbinical books of Jasher; one is a 'Treatise on the Jewish Laws,' written by Rabbi Ilam in the 13th century, and printed at Cracow in 1617; the other, pretends to be an explanation of the Pentateuch and Joshua, of which it is so much a mere repetition as to excite suspicion of its genuineness. The original, it is stated, was found at the time of the destruction of the Temple by Titus; it was preserved at Seville, and was printed in Hebrew at Venice in 1613. It has since been translated, and published by Mr. Noak, in New York; and the translator maintains that *this* is the book referred to in Joshua and in Samuel. Dr. S. P. Tregelles, in his edition of Horne's 'Introduction to the Scriptures,' (1856), says, "in character it ranks below most apocryphal books and similar forgeries."

Dr. W. J. Donaldson published in 1855 a book entitled 'Jashar Fragmenta Archetypa Carminum Hebraicorum in Masorethico Veteris Testamenti textu passim tessellata. Collegit, ordinavit, restituit, in unum corpus redegit, Latine exhibuit, Commentario instruxit.' In this work he endeavours to prove that the books of the Old Testament were none of them written before the time of Solomon, and then only as fragments, which he thinks formed the book of Jasher, or of the Upright; and that these fragments were subsequently worked up into the shape of the existing books, at least as far as the Psalms. This theory he supports by selecting certain passages, which he styles "the very marrow of divine truth," and considers them as the genuine fragments referred to in the passages in Joshua and in Samuel. It is scarcely necessary to give references to the passages so selected, but the work was printed at Berlin in Hebrew and Latin. To this, in 1855, the Rev. J. J. S. Perowne published a reply—'Remarks on Dr. Donaldson's Book, entitled Jashar;' in which he points out the unsatisfactory base of such a theory, founded on an arbitrary selection of passages "culled by editorial skill out of the midst of works already existing as a whole, published as a whole, and bearing internal evidences of order and unity of design." They extend from Genesis i., of which two verses are selected, to the dedication of the temple, Psalm lxviii.

JASON. [ARGONAUTS.]

JAUNDICE (from *jaune*, yellow) is the name given to those diseases in which the excretion of the bile being prevented, it is retained in the blood, or re-absorbed, and being diffused throughout the system, gives a yellow colour to the skin, and all the other tissues and secretions.

The name is however very indefinite, because the cases in which the separation of the bile is prevented are various. Everything, for example, which obstructs the main trunk of the bile-ducts, as gallstones [CALCULUS, BILIARY], or other foreign bodies filling its canal, certain morbid alterations of the liver or duodenum, or of the duct itself, tumours and enlargements of adjacent organs, will alike mechanically produce jaundice, though their other symptoms differ widely. Again, it is often a symptom of inflammation of the liver, as especially in yellow fever, and of inflammation of the duodenum. But the most frequent cases are those which do not appear to be the consequence of any organic disease, but are accompanied by the symptoms of general disorder of the digestive organs, as nausea or vomiting, thirst, and loss of appetite, confined or irregular condition of the bowels, headache, and general uneasiness. These cases generally come on suddenly, as a sequel of common diarrhœa, or in the dyspeptic and those of a sedentary habit, or whose bowels have been long inactive. It is often difficult to say what prevents the excretion of the bile; sometimes it is separated from the blood in too viscid a form; sometimes mucus appears to obstruct the duct; in many cases there is probably spasm of the duct, as in those which occur after violent fits of anger or other mental affection; and in some a larger quantity of bile appears to be formed than can be conveyed away with proportionate rapidity.

It is impossible that any one mode of treatment should be adopted for a symptom depending on such varied causes. Where the obstruction is mechanical, the jaundice is of course curable only by the removal of its evident cause; and in inflammation of the liver it is but a symptom of a more important disease, to which the treatment must be directed. In the more common cases, which, as distinguished from these, are sometimes called functional, the treatment should consist chiefly of small doses of mercury, and active purgatives containing the neutral salts. Warm baths and opium should be used, if there be any spasmodic pain of the right side; and leeches, if any inflammatory pain or tenderness be felt. A mild diet and the avoidance of all stimulant drinks or food should be carefully enjoined.

JERVINE ($C_{60}H_{45}N_2O_5 + 4$ aq.). *Jervina*, a vegetable alkaloid found with veratrine, colchicine, and sabadilline in white hellebore root. It is white and crystalline, and melts when heated into an oleaginous liquid; at a higher temperature it takes fire, and burns with a sooty flame, without any residue. It is nearly insoluble in water, but dissolves in alcohol.

Its compounds with hydrochloric, sulphuric, and nitric acids, are but slightly soluble in water and acids; the acetate dissolves readily in water; ammonia decomposes the solution and occasions a bulky precipitate of jervine.

JESUITS; SOCI'ETAS JESU. [LOYOLA, in BIOG. DIV.]

JETSAM. [FLOTSAM.]

JEWELLERY; JEWELLING. It may be desirable to explain briefly the sense in which the words *jewellery* and *jewelling* are understood, as manufacturing terms.

Jewellery.—A jewel is a gem or precious stone, such as the diamond, sapphire, ruby, &c. The cutting of these gems, to give them a particular contour as well as reflecting facets, is the art of the lapidary, who works with very small sharp-edged wheels; the wheels are made to rotate rapidly; and their edges are touched with the powder of some substance harder than that which is to be worked upon; the gem is thus ground away rather than cut—although it is sometimes severed into portions by a process midway between cutting and slitting. The different gems themselves are described under their proper names, as objects of mineralogy, in the NATURAL HISTORY DIVISION of this Cyclopædia; the mode of cutting will be sufficiently understood by reference to many of those articles, to CAMEO and EMERY, and to the latter portion of the present article; while the process of making artificial or factitious gems occupies one of the sections in GLASS MANUFACTURE.

The word *jewellery*, however, has a wider sense than this. It comprises the *setting* of precious stones, and also the manufacture of small ornamental works in gold and silver, even when no precious stones are employed in them. The line of distinction between a goldsmith and a jeweller is not very marked, so far as the original meaning of the word is concerned; but there is a certain well-understood trade distinction. Goldsmith's work, under the general name of *plate*, comprises the articles which are stamped at Goldsmith's Hall and similar places; while *jewellery* comprises the smaller articles which are not so stamped.

There are great differences in the quality of the gold employed. Absolutely pure gold being technically called "24 carats fine," all other gold is named according to the ratio between fine gold and the alloy, estimated in 24ths. The alloy may be silver, or copper, or a mixture of both. Old *standard* gold used to have, and *sterling* gold still has, 22 of gold to 2 of alloy; new standard has 18 to 6. None below this can receive the "hall mark," or Goldsmith's Hall stamp. Gold of lower quality is often known by its value per ounce, as 60*s.*-gold, 40*s.*-gold, &c. Gold as high as 22 carats can rarely be used in jewellery; it is too soft. The so-called *fine*-gold of the jewellers is now usually about 16 carats; if meant to imply that the gold is pure, the word is of course, a deception. The announcement in shop-windows, "Fine gold chains, weighing 5 sovereigns each, for *5l.*," is little less than a fraud. Indeed, as ordinary purchasers have no means of testing the quality, there is scarcely any limit to the debasement of the metal employed. Plate *must* not be below a certain standard; jewellery *may* be, and *is*—in other words, *pure*, *sterling*, and *standard* gold have definite meanings; whereas, *fine* and *jewellers'* gold have not. It will thus be understood how gold chains, and such like articles, vary so much in value without varying much in appearance. By using a little more silver in the alloy, the tint is heightened; by using a little more copper, it is deepened; and thus the tint of pure, or nearly pure, gold can be very nearly imitated. A troy ounce of absolutely pure gold is worth *4l. 4s. 11½d.*; of *sterling* gold (22 carats), *3l. 17s. 10½.d*; of new *standard* gold (18 carats), *3l. 3s. 8½d.*; of 12-carat gold, *2l. 2s. 5½d.*; of 8-carat gold, *1l. 8s. 3½d.*—and so on; therefore, the value of an ounce of so-called gold is wholly indefinite, unless the ratio of alloy be stated. Some jewellers' gold is as low as 3 carats, not worth more than about 9*s.* per oz. The makers of cheap chains, pencil-cases, lockets, &c., have discovered that if zinc be used instead of silver as an alloy, the appearance is improved; and thus the intrinsic value of the gold is brought lower than ever.

There are many compositions and many imitations of gold, used by artificers. A *liquid* gold is formed from a solution of terchloride of gold agitated with ether; it is used for producing devices on steel, &c., by leaving a coating of pure gold when dry. *Gold bronze*, or *gilding powder*, is often made on a small scale by grinding up gold-leaf with honey. *Dutch gold*, also called pinchbeck and tombac, is made in Holland and Prussia, by combining 11 parts of copper and 2 of zinc, and rolling the compound into thin sheets. *Grain gold* consists of nearly pure gold, employed in making various preparations. A *factitious* gold, consisting of copper 16, platinum 7, and zinc 1, presents nearly the colour and appearance of gold of 16 carats. *Mosaic gold* is made from bi-sulphuret of tin, or from various brassy compounds of metals. Messrs. Mourier and Vallent, in 1857, introduced an *artificial* gold for ornamental work, which is said to be fine-grained, malleable, fusible for casting in a mould at a low heat, and susceptible of a good polish. It consists of copper 100, tin 17, manganese 6, sal-ammoniac 4, quicklime 2, and tartar 9.

The processes of jewellery, as a branch of goldsmith's work, need no description; they comprise small or fine examples of casting in moulds, stamping with dies, wire-drawing, hammering and filing, burnishing and lacquering, &c.

Jewelling.—Jewelling, unlike jewellery, is a term wholly applied to gems, and not likewise to working in gold. It is especially applied to the jewelling of watches. This consists in setting diamonds, rubies, sapphires, chrysolites, or other hard stones, in the frame-plates and other parts of watches, in such a manner that the pivots of the watch may act in holes made in these stones. There are two kinds of jewelled holes necessary in watches, one of which is merely a perforation through the stone; the other consists of a perforated piece, and a piece called an end-piece. The province of the watch-jeweller is to select the stones, and, except in the case of diamonds, to grind, polish, turn, drill, and set them into the frames or other parts of the watch in such a manner that the holes in the stones may correspond exactly in position with holes previously made by the watch-finisher or escapement-maker. A hole *without* an end-piece is thus made. The hole in any piece to be jewelled having been made in its proper place by the finisher, the piece is so fixed in a lathe by the jeweller that the hole shall be perfectly concentric with the centre of motion; this hole is then enlarged by turning, and afterwards so formed that a small circle of brass which contains the stone, and which is called the setting, may have a cavity to rest in, without the possibility of its going through the plate or piece in which the hole has been made. After the setting has been fitted to the cavity, and adjusted so as to be flush with the plate, two screws are inserted in the plate so near to the cavity which contains the setting that the edges of the screw-heads project a small distance over the edge of the setting, and thereby secure it in its place. When a hole *with* an end-piece is required, the same process is adopted, but two stones are required for each hole instead of one; and the first, or perforated stone with its setting is sunk into the cavity a sufficient distance below the surface of the plate to allow of the reception of a second setting, containing a stone which resembles in form a small slice cut from a sphere about the size of a shot, its form being plano-convex. The edge of this second setting is left flush with the plate or piece in which the cavity is made; and two screws being inserted, as in the former case, the two settings are secured at once. In the holes already described the stones are secured in their brass settings in a manner somewhat similar to that in which opticians set many of their glasses in telescopes: namely, by turning a place to receive the stone, and leaving a fine edge of brass, which is subsequently rubbed over the edge of the stone with a burnisher. When a diamond end-piece is used, it is usually set in steel, into which it is brazed, the diamond being a stone which will allow of heat sufficient for that purpose. After brazing, the steel is turned into shape, polished, and blued.

The apparatus necessary for the jeweller to carry on his business consists of a small lathe; small gravers for turning brass and steel; a quantity of rough diamond in fragments, technically termed *bort*; small mills or circular discs of metal (usually copper) for grinding the stones into shape; diamond powder of various degrees of fineness for polishing; and turning tools made by cementing small pieces of bort into a notch made in the end of small brass wires and fixed in proper handles. In the preparation of a stone for a jewel-hole, it is necessary first to charge a copper disc about the size of a penny piece, and out of which it is frequently made, with bort; the mill thus prepared is fixed unto the mandrel of the lathe, which is put in motion by a band from a rather large foot-wheel, the mill making from 6000 or 7000 to more than 20,000 revolutions in a minute, the latter velocity being given only in the act of polishing. The stone to be formed is then taken on the end of one of the fingers of the right hand and applied to the surface of the bort mill, which is kept constantly wet with water applied by the fingers of the left hand, and in a few seconds a flat surface is produced on a stone of the most irregular form; the flat surface is then placed next the finger, and a similar surface is produced parallel to the former, until the stone is of such a thickness as is required. The stone is then placed, by means of cement, on a small chuck in the lathe; and with one of the before-mentioned bort tools is turned into the proper shape for setting. The hole is also drilled either with a steel drill and diamond-powder and oil, or with a drill made of bort or small fragments of diamond. The piece of stone, or hole, as it is called, is also turned with a hollow, or countersink, to receive the oil necessary for the lubrication of the pivot. The stone is afterwards detached from the lathe, and its flat or parallel surfaces polished by rubbing it on a piece of plate-glass, previously charged with a small quantity of diamond-powder and oil. When an end-piece is required the same process is gone through, except that the drilling is omitted, and the spherical side of the stone is polished by using a piece of brass with a hollow end to suit the convexity of the stone. The jeweller also makes use of a small spirit-lamp to heat the cement when he applies it for the purpose of securing the stones upon the chucks in the lathe. The end-pieces, when real diamonds are used, are what are called rose diamonds, and are procured from Holland, where they are cut.

It may here be added that small jewels, such as bits of ruby, are sometimes used for the nibs of pens; and that diamonds, rubies, and garnets, are made into exquisitely minute lenses for microscopes.

JEW'S-HARP, a musical instrument of the simplest and rudest kind, consisting of an iron frame, resembling in form the handle part of an old-fashioned corkscrew, in the centre of the upper and wide part of which is riveted at one end an elastic steel tongue, the extremity of which, at the free end, is bent outwards to a right angle, so as to allow the finger easily to strike it when the instrument is placed to the mouth and firmly supported by the pressure of the parallel extremities of the frame against the teeth.

Mr. Wheatstone has shown that the sounds of the Jew's-harp mainly depend on the reciprocation of columns of air in the mouth of the performer, and that these sounds are perfectly identical with the multiples of the original vibrations of the instrument. Hence its scale must necessarily be very incomplete; but by employing two or more instruments the deficiencies are supplied. Some years ago, an ingenious foreigner, M. Eulenstein, exhibited in London, at the Royal Institution, and afterwards at various concerts, his very extraordinary talent on the Jew's-harp. He used sixteen instruments of different sizes, and was thus enabled to modulate into every key, and to produce effects not only original, but musical and agreeable.

JEWS (Ἰουδαῖοι and *Judæi* in Greek and Latin, *Jehudim* in Hebrew), in its widest acceptation, is used as synonymous with Hebrews, or Israelites, but in a more restricted sense it means the inhabitants of the kingdom of Judæa as it existed in the time of Jesus Christ, and whose descendants are now scattered over all the world. The history of this people previous to the time of Christ is contained in the Old Testament and in Josephus, and need not be repeated here. The resistance made by the Jews to the power of Rome resulted, first, in the dominion of the Asmonean princes, of whom an account will be found under ASMONEANS, in the BIOG. DIV.; and, later, in their having been forced by tyranny into rebellion, in the destruction of the Temple by Titus. The Jews then became a dispersed people; and, therefore, from about the time of the birth of Our Saviour we give a slight sketch of their history. It has to be observed, however, that the character of the Jews had undergone a considerable change during their Babylonish captivity. They had become more exclusively attached to their country and their laws, and we hear no more of their proneness to idolatry after that epoch, as in former times. They strictly avoided intermarriage with foreigners, and assumed in every respect that unsocial spirit towards all except their own community for which they have been so often reproached. Adversity had soured their minds, while the expectations of a Messiah who was announced by their prophets roused the national pride. The doctrine of the immortality of the soul, which is not mentioned in the Mosaic law, was also introduced, especially among the great sect of the Chasadim, or Pharisees.

The last of the Asmonæan dynasty was put to death by Herod, son of Antipater the Idumæan, who, with the support of the Romans, became king of Judæa B.C. 38. [HEROD THE GREAT, in BIOG. DIV.] He died in the same year that Christ was born, although in the common chronology the birth of Christ is placed four years later. With Herod the independence of Judæa may be said to have expired. His son Archelaus was appointed ethnarch of Judæa Proper, Idumæa, and Samaria; his brother Herod Antipas had Galilee and Peræa; to Herod Philip were given the provinces of Trachonitis, Batanæa, and Gaulonitis, east of the Jordan; and another Philip had Ituræa. Thus the dominions of Herod were dismembered between four of his sons, who are accordingly styled Tetrarchs in the New Testament. Archelaus was summoned to Rome after a reign of nine years, to answer certain charges brought against him by his subjects, and was banished by Augustus to Vienne in Gaul. Judæa thus became a Roman province, or rather a district dependent on the great province or prefecture of Syria, though administered by a special governor, a man usually of the Equestrian order. This is the state to which Judæa was reduced in the time of Our Saviour. The Jews, however, continued to enjoy the exercise of their religious and municipal liberties.

Under the reign of Claudius, Herod Agrippa, grandson of Herod the Great, who had been already appointed by Caligula ethnarch of Galilee, was appointed king of Judæa and all the former dominions of his grandfather; but he died three years after, at Cæsarea in Palestine, A.D. 44. This is the Herod mentioned in chapter xii. of the Acts. His son, called likewise Herod Agrippa, was then a minor, and Judæa relapsed into a Roman province. In A.D. 53 Claudius gave to Agrippa the provinces east of Jordan, which had belonged to Philip the Tetrarch, and Nero added to them part of Galilee. But Judæa and Samaria continued to be administered by Roman procurators. Herod, however, was entrusted by the emperor with the superintendence of the Temple and the right of appointing and deposing the high-priest at Jerusalem, and he occasionally resided in that city, while the Roman governor generally resided at Cæsarea. This second Herod Agrippa is the one mentioned in Acts, xxv., xxvi., there styled King Agrippa, whom St. Paul addressed in so impressive a manner in his defence. Agrippa was present at the final catastrophe of Jerusalem.

A succession of more than usually rapacious Roman governors—Felix, Albinus, and Florus—had driven the Jews to the verge of despair. A revolt took place, beginning at Cæsarea, which was only terminated by the taking of Jerusalem in A.D. 70. Still the Jewish population was by no means extirpated from the country, and we find them rising in vast numbers in the reign of Hadrian, and again engaging the Roman legions commanded by Severus. They were however overpowered with immense slaughter, and the second desolation of Judæa took place.

The dispersion of the Jews over the world, which is commonly dated from the destruction of Jerusalem, had in reality begun long before. The Ptolemies had transplanted large colonies of them into Egypt, Cyrene, and Cyprus; and Antiochus the Great settled great numbers in the towns of Asia. In the time of Cicero (' Pro Flacco ') there was a wealthy Jewish community in Italy. A passage of Philo, in his letter of Agrippa, enumerates the countries in which the Jews were settled in the time of Caligula: Egypt, Syria, Pamphylia, Cilicia, the greatest part of Asia Minor as far as Bithynia, the shores of the Euxine, Macedonia, Thessaly, Ætolia, Attica, the Peloponnesus, Cyprus, and Crete, besides the countries beyond the Euphrates; for at the end of the Babylonish captivity many Jews voluntarily remained in Mesopotamia, where they continued to form for several centuries a considerable community, alternately under the Parthian and Roman dominion.

Ascribing their continued misfortunes to the non-observance of the Mosaical laws, the Jews now established schools for the stricter inculcation and study of them; and that of Tiberias was particularly celebrated. From these schools issued the Mishna and the Gemara; the first by Rabbi Jehuda, the second by Rabbi Ascha and his disciples; the whole forming the Babylonian Talmud. Many learned Rabbis distinguished themselves as opponents of the constantly increasing Christian faith. When the Eastern Empire had adopted Christianity, the Jews, who had hitherto lived undisturbed, were placed under many restrictions. They were forbidden by Constantine to receive Christian converts, or to possess Christian slaves. Under Constantius, his successor, a tumult in Alexandria, in which they were implicated, led to fresh enactments against them, and to additional taxation; and subsequently Tiberias was burnt, and the school destroyed. Under Julian they were favoured, and he proposed to restore the temple, a project never completed. His successors renewed the severities against them, and in A.D. 415, after a tumult, 100,000 Jews were expelled from Alexandria.

Theodoric and the other Gothic kings of Italy protected the Jews. During the frequent wars and invasions of that period, the Jews had the slave-trade of Europe in a great measure in their hands; and Pope Gregory I. and several councils interfered to prevent their abusing the power which they had thus acquired over the persons of Christians. That wise and humane pope, in his pastoral letters, bewails and denounces this traffic, which was carried on in Italy, Sicily, Sardinia, and France; he directs the bishops to interfere so as to prevent Jews from retaining Christian slaves when a proper price was offered for them. On another occasion he directs that those Christian slaves who had been long in possession of Jewish landed proprietors should be considered as villains attached to the soil, and should not be transplanted or sold away; he also entreated the Frankish kings to banish the traffic in slaves from their dominions.

Justinian was one of the first who enacted really oppressive and intolerant laws against the Jews. One of these laws declared that all unbelievers, heathens, Jews, and Samaritans could neither be judges, nor prefects, nor fill any other dignity in the state; and another enacted that in mixed marriages between Jews and Christians the chief authority over the children should rest with the Christian parent. The Longobards in Italy maintained the severities that Justinian had imposed upon the Jews; and by the West Goths in Spain they were forbidden to hold their sabbath or celebrate their Passover according to the Mosaical law.

The Jews however were too numerous and strong to be annihilated by imperial edicts: they had even the power of revenge. When Chosroes II. invaded Syria, the Jews of Palestine rose to join the Persians, with whom they entered Jerusalem, then a Christian city, and perpetrated a dreadful slaughter of the Christian inhabitants. They are said to have purchased at a cheap price the captives of their allies the Persians, for the sake of murdering them. The victories of Heraclius however put an end to their momentary triumph.

The rise of Mohammedanism brought an unfavourable change to the Eastern Jews. For a short period a Jewish dynasty was seated on the throne of Yemen in Arabia, but it was dispossessed by a king of Ethiopia, about the beginning of the 6th century. Jews however still continued numerous in Arabia; Mohammed endeavoured at first to win them over, but though at first they gave him some support against the pagans, they would not acknowledge a descendant of Hagar the bondwoman as the greatest of prophets, and Mohammed treated them without mercy. Under the Caliphs his successors they were protected on the easy terms of paying tribute, and as they made no resistance, they experienced not only protection but even encouragement from their new masters, whom they followed through their tide of conquest along the coast of Northern Africa. They also contributed materially to the triumph of the Crescent in the Spanish Peninsula. About the middle of the 8th century, a sect of Jews separated themselves from the main body, who were called Karastes. Their founder was Anan, who lived in Babylonia. This sect, which disclaimed the traditions of the Rabbis, and rejected the Talmud, spread itself widely through Palestine, Egypt, Syria, and Arabia, and for many years had an acknowledged chief, who dwelt at Cairo.

The intolerance the Jews had experienced in the Spanish Peninsula from the Gothic kings had driven large numbers to the opposite shores of Africa, whence many returned with the Saracen invaders; and the munificence of the Mohammedan princes towards them indicates that by their knowledge of the country the Jews had been highly instrumental in advancing the conquest. In Moorish Spain the Jews had really a golden age, which lasted for centuries. There they cultivated science and learning; and the names of Benjamin of Tudela, Isaac of Cordova, Hasdai, the confidant of Abderrahman, and a host of others, attest their proficiency. Rodriguez de Castro (' Bibliotheca Española ') and Vicente Ximeno (' Escritores del Reyno de Valencia ') give notices of the writings of the Spanish Jews. At the same time they were thriving in the East under the caliphs of Bagdad, whose favour they enjoyed, at least till towards the end of the 10th century; and in Egypt, where they were protected by the Sultan Saladin, who employed the celebrated Maimonides as his physician.

Although at first partially employed by the Christian princes of Spain on account of their financial and scientific abilities, the position of the Jews became gradually more irksome as the Moorish power declined. In 1391 an archbishop of Sevilla excited the populace against them, and it is stated that of 7000 families, one half were slain, while 200,000 were enumerated as real or pretended converts to Christianity. Even these were not left in peace. The regular Inquisition established under Ferdinand and Isabella undertook the task of punishing all relapsed converts. As for the unconverted Jews, the edict of 1492, made at the instigation of the Inquisitor Torquemada, banished them all from the kingdom. The number of Jews thus expelled from Spain has been vaguely estimated at half a million, and even 800,000. They were allowed to carry away or sell only their moveables. Few of them consented to embrace Christianity in order to remain. Soon afterwards they were driven away from Portugal also with circumstances of still greater barbarity. Many perished, and others took refuge on the African coast. The expulsion of the Jews and that of the Moors or Moriscoes drained Spain of its most useful subjects. It was not till 1837 that even a slight amount of toleration was granted to them; but the numbers in the Peninsula even now are so few that they are not given in the general estimate of the total number of Jews; which for Europe may be about 3,500,000, as the ' Almanach de Gotha ' for 1860, gives details amounting to 3,136,499, and does not include Great Britain, Bavaria, Belgium, Electoral Hesse, or Wurtemberg.

Charlemagne protected the Jews like his other subjects: they filled municipal offices; they were physicians and bankers; and Isaac, a Jew, was chosen by that emperor as his ambassador to Haroun al Rashid, caliph of Bagdad, a mission which was considered of the greatest importance at the time. The Jews enjoyed the same or even greater influence under Louis le Debonnaire and Charles the Bald, but towards the end of the latter reign the clergy began afresh to show their hostility. The Council of Meaux re-enacted the exclusion of the Jews from all civil offices; but it was under the third or Capet dynasty that the Jews suffered actual persecution in France. Philippe Auguste, pressed by the wants of an empty exchequer, and perhaps also by the reports of fanatics, who charged the Jews with all sorts of crimes, banished, in 1180, all the Jews from his dominions, confiscated their property, and declared all debts due to them to be annulled. About twenty years afterwards the Jews were allowed to re-enter France, which they did in great numbers. This was the beginning of a series of alternate proscriptions and relaxations, continued under the following reigns for about two centuries, until they were expelled under Charles VI. in 1394. Although the laws continued very severe against the Jews, and were sometimes invoked with much zeal, many continued to reside in France. The Revolution of 1789 brought them relief; all Frenchmen were declared equal; and throughout the political and constitutional changes which have since taken place in France, their rights have been respected. Napoleon I. in 1806 assembled a sanhedrim at Paris, and submitted to them twelve questions concerning the moral and social doctrines and discipline of the Jews. Their answers being found satisfactory, an ordinance was issued giving the Jews a regular organisation throughout France. They are subjected to the conscription, and are assessed to taxes like the rest of their countrymen; and they are eligible to all political employments, in which some of them have reached the highest ranks. The Jews in France, in 1856, numbered 73,995.

In Germany perhaps the Jews have suffered the most persecution, although they have always been numerous there, especially in the free towns. Besides the severities of the laws, they were exposed to sudden bursts of popular fanaticism. They were massacred at the cry of "Hep," "Hep," the initials of the word "Hierosolyma est perdita." St. Bernard and Pope Eugenius III. loudly reprobated these atrocities. These persecutions almost of necessity drove them to the practice of usury, as affording the best security against their effects being plundered by a mob. In 1782 the writings of Lessing, Mendelssohn, and others began to produce their effects, for in this year an Austrian edict for a limited toleration was issued; by 1803 the capitation tax was removed from them in all the states of the German empire; by 1811 the rights of citizenship had been extended to them in most of the smaller German states; in 1812 they were placed nearly on an equality with their fellow subjects in Prussia; by 1833 this had extended to all the other states; in the disturbances of 1848 they were promised an entire equality, but the promise has not been as yet fulfilled. The Jewish population in Germany is large; in the Prussian territories, in 1855, they numbered 234,248; in the Austrian empire they amounted to 853,304. Among the smaller states, ducal Hesse has the largest proportion, there being 28,700 Jews in a population of 845,571.

In Italy the Jews seem to have enjoyed greater though not always uninterrupted security. They were expelled from Naples and Sicily by Charles V., although he afforded them a moderate amount of protection in the empire. But in the Italian republics and trading towns the Jews formed a numerous and prosperous body, from their commercial aptitude, and more particularly from their trading intercourse with the Levant. In the Papal territories they were sometimes tolerated and sometimes persecuted; but here, as elsewhere, the Reformation has worked in their favour. They were, however, confined to a particular quarter in the towns, called the ghetto. Sardinia permitted them to become possessors of landed property, and this privilege, with others, will now be extended to a wider circle. In Italy there are supposed to be 47,000 Jews.

In Holland, Denmark, and Sweden, more especially since the Reformation, the Jews have lived undisturbed; and in Holland they have long formed a highly flourishing, numerous, honourable, and intelligent community, amounting in 1859 to 64,070 in number.

In Poland, Casimir the Great, about 1360, afforded an asylum to the Jews when they were being persecuted in almost every other part of Europe. They became numerous, and diffused themselves widely into Russia. Their united numbers in those states in 1858 is given as 1,821,678; and though not in all respects on an equality with the citizen, they enjoy many privileges, and are generally above the serf. They are seldom cultivators, and in many districts have almost entire possession of some peculiar profession or trade.

Throughout the dominions of the Sultan the Jews are allowed to settle and follow their trades, though looked upon with scorn by the Osmanlees; and they number, it is stated, 300,000. In the regencies of Barbary they have settled likewise in great numbers.

(Jost, 'Allgemeine Geschichte des Israelitischen Volkes;' Millman, 'History of the Jews;' Ersch and Gruber's 'Allgemeine Encyklopädie;' Meyer's 'Grosse Conversations-Lexicon;' 'Almanach de Gotha,' 1860.

It does not appear at what time the Jews found their way to this island, but they were settled here in the Saxon period, and as early as A.D. 750. From the time of the Conquest the Jews in England rapidly increased in number. Under the first three Norman kings they lived undisturbed, so far as we are informed, and apparently acquired great wealth. But under Stephen and his successors they suffered grievously from the rapacity of the kings and the bigoted intolerance of the people. The cruel persecutions which they experienced from all persons, both lay and ecclesiastic, poor and rich, are fully attested, not by their own writers, but the evidence of their enemies. Finally, in the reign of Edward I., about 1290, all the Jews were banished from the kingdom. Their numbers at that time are conjectured (but on what grounds we are not aware) to have been between 15,000 and 16,000. It was not till after the Restoration, 1660, that the Jews again settled in England; and though under the Protectorate they had entered into negociations with Cromwell to obtain permission to enter the island, nothing seems to have been done in the matter, and those who have investigated the subject bring forward no proof of leave being formally granted to them to return. After the Restoration it seems probable that they came in gradually without either permission or opposition, and since that time foreign Jews have been on the same footing as other aliens with respect to entering the country. In the year 1753 an act was passed to enable foreign Jews to be naturalised without taking the sacrament; but the act was repealed in the following session, under the influence of the popular feeling, which was most strongly opposed to the measures of 1753. Since that year they have lived in the United Kingdom unmolested.

During their residence in England, up to their banishment in the time of Edward I., the Jews were considered as the villains and bondsmen of the king, a relation which seems to explain the power over their persons and property which was assumed and exercised by the king in the most oppressive manner. They however could purchase and hold land, subject only to the right of the king, whatever it might be, to levy heavy taxes on them and seize their lands if they were not paid. By the act of the 55th of Henry III. the Jews were declared incapable of purchasing or taking a freehold interest in land, but might hold, as in time past they were accustomed to hold, houses in the cities, boroughs, and towns where they resided. Another act, 3 Edward I., forbade Jews from alienating in fee, either to Jew or Christian, any houses, rents, or tenements which they then had, or disposing of them in any way without the king's consent; they were permitted to purchase houses and curtilages in the cities and boroughs where they then resided, provided they held them in chief of the king; and they were further permitted to take lands to farm for any term not exceeding ten years; such permission however was not to continue in force for more than fifteen years from the date of the act. Since the time of their banishment no statute has been passed which in direct terms affects the right of the Jews to hold real estates in England; and it has been a matter of dispute whether they could legally hold such estate.

In March, 1828, the first step was taken towards their emancipation by the Corporation of London rescinding their order of 1785, that baptised Jews should not be admitted to the freedom of the city. From 1831 repeated Bills were brought into the House of Commons for the removal of the political disabilities of the Jews, which in 1836 and 1842 were passed in the lower house but rejected by the Lords. In August, 1846, however, an act was passed (9 & 10 Vict. cap. 59,—Religious Disabilities Relief Act), by which they were enabled to hold landed property, to endow schools and other charitable foundations, and repealed the provisions as to their dress, the necessity of attending Christian worship, and as to their wearing a badge of yellow taffeta. The next year another act legalised their marriages. In 1855 their places of religious worship were placed on the same footing as those of Roman Catholics and Protestant Dissenters. By the Reform Act in 1832 they had been admitted to the exercise of the elective franchise; and by the 21 & 22 Vict. cap. 49, passed July 23, 1858, they were made eligible for seats in Parliament, by the omission from the usual oath "on the true faith of a Christian," in any case where the person elected shall declare himself to be a Jew.

The number of Jews in the United Kingdom has been estimated at 30,000, which is probably under the real number. Of these, 20,000 are supposed to be in London; while in Scotland and Ireland their numbers are few. According to the Census of 1851, the Jews in England and Wales had 53 synagogues, with accommodation for 8438 worshippers; in Scotland only one synagogue, accommodating 67 worshippers, at Edinburgh. They are also numerous in the British colonies and in the United States of America. They are to be found in every quarter of the known world, even in China; and in Morocco and other parts of Africa, as well as in Asia, they are comparatively numerous; while in very few places is there now any active persecution against them or their faith.

JIG, or GIGUE, an animated quick dance-tune, in six-eight time, to be found in the sonatas of Corelli, Handel, and other composers till towards the middle of the 18th century. The *jig*, or at least the name, is unknown in modern music; though in a French work of recent date, we are told that it is still in use in England.

END OF VOLUME IV.
